Blackheads, whiteheads, femoral head

Question

A 17-year-old female presented with months of increasing right hip pain, years after internal screw fixation for slipped upper femoral epiphysis. Two weeks following elective screw removal, she re-presented with a painless, erythematous, fluctuant lump beneath her surgical scar. The collection was drained, although culture-negative, and she was discharged on oral cephalaxin, only to re-present in identical circumstances four weeks later. MRI showed a large collection extending through fascia into the proximal femur medulla, highlighting the ghostly outline of the recently departed screw (Fig. 1). After repeated culture-negative drainage/debridement procedures, associated with prolonged immobility and complicated by deep vein thrombosis and pulmonary embolism, a Gram positive bacillus was eventually identified by prolonged culture and 16S ribosomal RNA PCR.

What was the organism? (Answer on page XXX)

Paediatricians have long been aware of the key role played by Propionibacterium acnes in acne vulgaris (1). There is increasing recognition that P. acnes also causes indolent invasive infections, particularly associated with surgery and prosthetic materials where biofilm formation is a key virulence factor (2). These infections are characterised by long periods from surgery to symptoms, and for lack of inflammation. Anaerobic culture for at least 10-14 days is recommended for optimal recovery, and molecular methods can improve the yield of P. acnes (3).

While the organism is susceptible in vitro to multiple antibiotic classes (although not metronidazole), perioperative antibiotic prophylaxis (eg with first generation cephalosporins) does not prevent late infections, and clinical management is typically complicated. Antibiotics active in bacterial biofilms, such as rifampicin, are often used, and prosthesis removal and extensive debridement are usually required.

P. acnes often infects children and adolescents with multiple disabilities requiring orthopaedic and/or neurosurgical instrumentation. Prompt diagnosis and treatment is possible when their most involved clinician, their paediatrician, is aware of the pathogenic potential of P. acnes and its typically atypical presentation.
