A Closer Look at Immune-Mediated Myocarditis
ABSTRACT

Immune checkpoint inhibitors (ICI) and tyrosine kinase inhibitors (TKI) have transformed the management of many malignancies. Although rare, immune-mediated myocarditis presents unique clinical challenges due to heterogeneous presentation, potential life-threatening consequences, and the time-critical need to differentiate it from other causes of cardiac dysfunction. Increasingly, TKI are being combined with ICI to promote immune modulation and improve efficacy. However, these combinations are associated with more toxicities. This series describes six patients with advanced melanoma who developed immune-mediated myocarditis whilst receiving an anti-PD-1 antibody or an anti-PD-L1 antibody plus a mitogen-activated protein kinase inhibitor. It provides a review of their heterogeneous clinical presentations, investigational findings, and treatment outcomes. Presentations ranged from asymptomatic cardiac enzyme elevation to death due to heart failure. We highlight the role of cardiac MRI (CMRI), a sensitive and non-invasive tool for the early detection and subsequent monitoring of myocardial inflammation. Five of the six patients exhibited CMRI changes characteristic of myocarditis, including mid-wall myocardial oedema and late gadolinium enhancement in a non-coronary distribution. Critically, two of these patients had normal findings on echocardiogram. Of the five patients who received immunosuppression, four recovered from myocarditis, and one died of cardiac failure. The sixth patient improved with cardiac failure management alone. Three of the four patients responding to ICI derived long-term benefit. Clinical vigilance, prompt multi-modal diagnosis, and multi-disciplinary management are paramount for the treatment immune-mediated myocarditis.

MAIN TEXT

INTRODUCTION

Immune checkpoint inhibitors (ICI) and molecularly targeted therapies have transformed the management of various malignancies[1, 2]. Increasingly, these agents are combined to exploit potential synergistic immune-modulation[3-6]. Recent trials of immunotherapy and targeted therapy combinations have demonstrated enhanced efficacy[4, 7], thereby fueling ongoing research to explore tyrosine kinase inhibitors (TKI) and immunotherapy combinations in a wide range of cancers.

Both TKI and ICI are known to cause drug-induced cardiotoxicity. TKI of the mitogen-activated protein kinase (MAPK) pathway, can cause reduced ejection fraction (EF), congestive cardiac failure (CCF), prolonged QT interval, hypertension, and acute coronary syndrome (ACS). Phase III studies of MEK inhibitor monotherapy and the combination of BRAF and MEK inhibitors reported reduced EF in 7% and 3-8% of patients, respectively[8-10].

The incidence of immune-related myocarditis due to ICI is around 1% with a mortality rate of up to 46%[11-13]. Immune-mediated myocarditis has a heterogeneous clinical presentation including reduced EF, CCF, arrhythmias, dyspnoea, palpitations, nausea, fatigue, weight loss, and/or chest pain[11-18]. Growing interest in combining ICI with TKI may lead to an increase in the incidence of drug-induced myocarditis given their overlapping toxicities and potential interaction[19]. The time critical need to differentiate myocarditis from other causes of cardiac enzyme rise and/or symptoms present unique management challenges.

The present series reports on six cases of myocarditis due to ICI monotherapy or a combination ICI and MEK inhibitor. Emphasis is placed upon the cardiac enzyme kinetics of each case and its relationship with immunosuppressive therapy. We highlight the role of non-invasive diagnostic tools and the current challenges faced in the management of treatment-related myocarditis.

MATERIALS AND METHODS

This series included six patients with metastatic melanoma who received ICI or a combination ICI and MEK inhibitor and presented with myocarditis between July 2016 and December 2018 at Peter MacCallum Cancer Centre in Australia. Institutional review board approval was obtained. Medical records were retrospectively reviewed for data on patient demographics, clinical presentation, diagnosis, and cancer and myocarditis treatment.
outcomes. Tumour responses were assessed using computer tomography (CT) and FDG-PET with responses determined using RECIST version 1.1 and PERCIST, respectively[20, 21]. Myocarditis was diagnosed using a combination of cardiac enzyme testing, CMRI, and transthoracic echocardiogram (TTE). Descriptive statistics were used for the reporting of clinical outcomes.

RESULTS

Four male and two female, with a median age of 72 (range: 60-88 years), presenting with myocarditis were identified. Four patients were treatment-naïve and two patients received prior anti-PD-1 therapy. The clinical presentation, investigational findings (Appendix B), and treatment (Appendix B) of each case is provided.

Case 1 & 2: Myocarditis in patients receiving anti-PD-L1 antibody plus MEK inhibitor

Case 1

A 74-year-old male with stage IV melanoma with distant skin metastases presented with fatigue, fevers, chills, anorexia, diarrhoea, and an acneiform rash 15 days after starting cobimetinib (60mg oral daily) and atezolizumab (840mg IV 3-weekly). This was following disease progression after 34 cycles of pembrolizumab.

Creatinine kinase (CK) was elevated at 1,165 U/L (normal range: 20-200 U/L) and high-sensitivity troponin T (hs-TnT) was elevated at 77 ng/L (upper limit normal (ULN): 20 ng/L). TTE demonstrated left ventricular ejection fraction (LVEF) of 55%. Electrocardiography (ECG) showed pre-existing left axis deviation. The patient’s presentation and findings on ECG and TTE were not suggestive of ACS. CMRI demonstrated midwall myocardial oedema and late gadolinium enhancement (LGE) of the basal, anterolateral, mid-inferior, and inferior segments in keeping with myocardial inflammation and necrosis (Figure 1).

Methylprednisolone (2mg/kg intravenous (IV) daily) was administered for three days and transitioned to prednisolone (2 mg/kg oral daily) which was weaned over eight weeks when CK and hs-TnT declined (Figure 2). Repeat TTE and CMRI eight weeks after starting corticosteroids showed preserved LVEF and reduced midwall oedema. The patient developed progressive disease 4.6 months after myocarditis diagnosis.

Case 2

A Closer Look at Immune-Mediated Myocarditis
A 60-year-old female with stage IV melanoma involving the lung, liver, and bone presented with nausea, vomiting, diarrhoea, and mucositis 13 days after commencing cobimetinib (60mg oral daily) and atezolizumab (840mg IV 3-weekly). This was following tumour progression after 12 cycles of pembrolizumab. She did not have any cardiac symptom, however, CK (377 U/L) and hs-TnT (455 ng/L) were elevated (Figure 2). ECG showed new flattened T waves in the inferior leads (II, III, AVF). LVEF was normal on TTE and did not demonstrate any regional wall motion abnormality. Methylprednisolone (1 mg/kg IV daily) was administered for three days. hs-TnT and CK normalised on day five and the patient was switched to prednisolone (1 mg/kg oral daily) which was tapered over six weeks. CMRI and coronary angiography performed several weeks after starting corticosteroids were normal. The temporal relationship between cardiac enzyme rise following the commencement of atezolizumab and cobimetinib, the rapid decline in cardiac enzymes upon starting corticosteroids, and the normal coronary vessels are suggestive of drug-induced myocarditis. The patient received two cycles of ipilimumab-plus-nivolumab in the context of intracranial progression three months after the resolution of these treatment-related toxicities. Treatment with ipilimumab-plus-nivolumab was ineffective and complicated by immune-related nephritis requiring prednisolone (1 mg/kg oral daily weaned over six weeks).

**Case 3 and 4: Myocarditis and Myositis**

**Case 3**

A 75-year-old male with stage IV melanoma involving the chest wall, omentum, and distant lymph nodes, and a prior history of ulcerative colitis presented with fatigue, weight loss, back and neck pain, truncal and limb girdle weakness 20 days after receiving a single dose of pembrolizumab. Initial CK was 13,025 U/L and hs-TnT was 2,978 ng/L. CMRI showed midwall LGE in the basal septal and inferoseptal segments (Figure 1). TTE showed preserved LVEF and there was no clinically significant ECG finding. The patient’s presentation as well as findings on ECG and TTE were not suggestive of ACS. Pulmonary function test excluded respiratory muscle involvement.

Pulse methylprednisolone (1 g IV daily) was administered for three days, then at 1 mg/kg for seven days before transitioning to oral prednisolone. Mycophenolate mofetil (building up 1.5 g oral twice daily (BD)) was introduced three weeks later when hs-TnT and CK remained persistently elevated at 113 ng/L and 513 U/L, respectively. CK and hs-TnT normalized six weeks after myocarditis diagnosis (Figure 2). Prednisolone was weaned over eight weeks and mycophenolate was stopped after six months.

A Closer Look at Immune-Mediated Myocarditis
Case 4

A 74-year-old female with stage IV melanoma with lung and small bowel metastases, medically controlled CCF, and type 2 diabetes presented with exertional dyspnoea eight weeks after the commencement of pembrolizumab. CK was 395 U/L and hs-TnT was 106 ng/L (Figure 2). TTE showed a decrease in LVEF from 57% at baseline to 35% and inferolateral akinesia. ECG showed a pre-existing right bundle branch block, deep Q waves in the inferior leads, and corresponding T wave inversion in the anterolateral leads. The patient declined coronary angiogram or CMRI at the time of diagnosis. Low molecular weight heparin was commenced since myocardial infarction was a possible differential. The patient was already on a beta-blocker, ACE-inhibitor and loop diuretic.

A CMRI performed three weeks after initial presentation to investigate persistently elevated levels of hs-TnT (100-200 ng/L) demonstrated epicardial LGE and oedema within the mid-inferolateral, anterior, basal, and lateral myocardial walls (Figure 1), as well as an old inferolateral partical thickness infarct. Methylprednisolone (2 mg/kg IV daily) was administered for four days and escalated to 1g daily for three days when cardiac enzymes failed to decline. Mycophenolate mofetil (1 g oral BD) was added. Following one month of immunosuppression, LVEF improved from 35% to 50%.

Five weeks into the prednisolone wean whilst still on 50 mg prednisolone and mycophenolate 1g BD, the patient presented with bilateral limb girdle weakness and CK had risen from 257 U/L to 3,769 U/L. hs-TnT incremented from 159 ng/L to 501 ng/L. An electromyograph confirmed symmetrical proximal myositis. Myositis antibody screen was negative. Muscle biopsy showed CD68+ histocytic infiltrate with a scant CD8+ and CD4+ T cells infiltrate. The patient received methylprednisolone (2 mg/kg IV daily) for three days, followed by oral prednisolone taper as well as intravenous immunoglobulins (IVIg) (2 g/day for three days), resulting in normalisation of CK after nine days and improvement in muscle strength. hs-TnT remained elevated at 100-200 ng/L even though a repeat CMRI showed reduction in LGE. Prednisolone was weaned over 10 weeks. The patient continues to receive mycophenolate and maintenance IVIg (0.4 mg/kg IV monthly).

Case 5: Myocarditis

An 88-year-old male with stage IV melanoma with locoregional and distant nodal metastases presented with dyspnoea and a pleural effusion after four doses of pembrolizumab. TTE showed LVEF had decreased from 48% at baseline to 18%. Initial hs-TnT was 2,146 ng/L.
and CK was within normal limits (Figure 2). CMRI demonstrated inferolateral akinesis and subendocardial LGE (consistent with previous infarction) plus scattered foci of mid-wall LGE (Figure 1). Methylprednisolone (1g IV daily) was administered for three days followed by oral prednisolone (2 mg/kg oral daily) tapered over six weeks. hs-TnT fell to 40 ng/L within eight days of initiating corticosteroids but failed to normalise completely. The patient’s symptoms initially improved with corticosteroids and diuresis but he declined further intervention and opted for best supportive care. He died of progressive CCF two months later. FDG-PET performed at the onset of myocarditis demonstrated a partial metabolic response.

Case 6: Dilated Cardiomyopathy and Colitis

A 61-year-old man with Stage IV melanoma with lung metastases presented with exertional dyspnoea after receiving 11 doses of pembrolizumab. TTE showed a decrease in LVEF from a baseline of 48% to 31%. ECG showed a pre-existing left bundle branch block. Standard cardiac failure treatment, including a beta-blocker, an angiotensin converting enzyme-inhibitor, and a loop diuretic, were commenced with symptomatic benefit. There was delay in recognising that the patient’s CCF was immune-related, hence corticosteroids were not commenced. CMRI performed 2 months after symptom onset demonstrated midwall LGE in the basal inferolateral wall and septum (Figure 1) and pembrolizumab was ceased. The LVEF improved from 31% to 45% on a TTE performed 6 months later, and normalised to 51% 18 months later. The patient developed immune-mediated colitis six months later and subsequently received prednisolone (1 mg/kg oral daily).

DISCUSSION

ICI-mediated cardiotoxicity is rare but potentially life-threatening. The incidence of immune-mediated myocarditis is possibly underreported in clinical trials given cardiac assessments were not routinely performed and trial patients may have less co-morbidities. Emerging evidence suggests that the real-world rates of cardiotoxicity is higher than previously reported[12, 22].

There is strong preclinical and clinical rationale for combining TKI and ICI given their complementary response profile and synergy in generating antitumour immunity. TKI including BRAF and MEK inhibitors have been shown to affect the tumour microenvironment and enhance tumour immunogenicity[3, 5-7, 23, 24]. Early clinical trials of ICI in conjunction with BRAF and MEK inhibition have demonstrated enhanced efficacy[7, 23, 24]. In renal cell
A Closer Look at Immune-Mediated Myocarditis

carcinoma, axitinib and pembrolizumab is a new standard of care and similar approaches of combining TKI and ICI are being investigated in multiple tumour types[4, 25, 26].

Both TKI and ICI have cardiac liabilities. However, it is unclear whether TKI and ICI interact to potentiate cardiotoxicity. TKI can cause ‘off-target’ cardiotoxicities due to the highly conserved nature of the ATP binding pocket of kinases across various organs[27]. Additionally, trametinib is highly selectively for MEK1/2; the MEK-ERK axis has been shown to be cardioprotective against oxidative stress, myocardial ischaemia-perfusion injury, and adaptive hypertrophy[28]. In contrast, immune-mediated myocarditis is postulated to be an exaggerated adaptive immune response against shared epitopes in the myocardium and tumour, and is hence characterised by extensive CD4+ T cell, CD8+ T cell, and macrophage infiltration[11]. Given inflammation causes oxidative stress, MEK-ERK inhibition may increase the susceptibility of cardiomyocytes to ICI-mediated inflammation. It is therefore possible that a higher rate of cardiotoxicity will be observed with combinatorial approaches.

Our series highlights the clinical heterogeneity of immune-mediated myocarditis. Clinical presentations included asymptomatic cardiac enzyme elevation, dyspnoea, and fatigue. Most patients presented within three months (range: day 13 to 214) of commencing ICI, which is consistent with published literature [12, 13]. In a safety review of 211 patients treated with trametinib, the median time to onset for cardiomyopathy was 63 days (range 16-153) [29]. It is possible that the combination of ICI plus MEK inhibition and/or prior PD-1 inhibition contributed to the early onset (within 15 days) of myocarditis in cases 1 and 2.

It is common for patients to experience multiple immune-related adverse events (irAE) [12, 13]. Four of the six patients developed a second irAE: two developed myositis, one developed colitis, and one developed nephritis. Myositis was the most common second irAE (25% of patients) in a series of 101 patients with immune-mediated myocarditis [13]. Another case series of patients with immune-mediated myocarditis showed 11% of patients developed colitis and 20% developed hepatitis[12]. It is critical to maintain vigilance for the emergence of other irAE if the patient’s symptoms cannot be explained by one unifying diagnosis.

Immune-mediated myocarditis requires multi-modal diagnosis. Whilst the current gold standard for its diagnosis is histological findings of endomyocardial lymphocyte infiltration with myocyte necrosis, myocardial biopsies are rarely performed because of its invasive nature and the risk of false negative findings[30]. Non-invasive investigations are an integral part of the workup of patients with suspected myocarditis. All five of the patients who...
underwent cardiac enzyme testing had elevated hs-TnT. A preserved EF, observed in two of
the six patients, does not exclude myocarditis[12, 31]. In a retrospective series of 35
patients with immune-mediated myocarditis, 38% of major adverse cardiac events (MACE)
occurred in patients with preserved EF[12].

Five of the six patients underwent CMRI. Four had characteristic findings of myocarditis,
including myocardial oedema on T2-weighted imaging and LGE in a non-coronary
distribution (Figure 1)[32]. Case two, the only patient with a normal CMRI, probably had
partially treated low-grade inflammation given the modest troponin and CK elevations. CMRI
is highly specific (91%) and moderately sensitive (67%) for the diagnosis of myocarditis[32].
CMRI may be normal in those with scattered or low-grade inflammation[30, 32]. CMRI
mitigates issues with sampling error and the risks associated with myocardial biopsy[30, 32].
A series of 16 patients showed early gadolinium enhancement at the diagnosis of
myocarditis was associated with worse long-term functional recovery and symptoms[33].
The utility of CMRI in prognostication and follow-up warrants further assessment.

FDG-PET is also emerging as a useful non-invasive tool for the diagnosis of myocarditis. In
a study of 65 patients with suspected myocarditis, FDG-PET demonstrated high specificity
(97%) and moderate sensitivity (74%) when compared to CMRI[34]. FDG-PET may
complement the use of CMRI by improving the detection of scattered or low-grade
inflammation which may not be visible on CMRI. The ability of FDG-PET to quantify the
degree of inflammation by measuring pathologic glucose uptake may be useful for
monitoring myocarditis and guiding immunosuppressive therapy, thus warrants further
prospective evaluation[34].

The management of immune-mediated myocarditis has been extrapolated from myocarditis
due to other aetiologies. The optimal dosing of corticosteroids and timing for the addition of
other immunosuppressants is unclear. Whilst the consensus for the initial steroid dose is an
equivalent of (methyl)prednisolone 1-2 mg/kg[35, 36], some experts suggest using
methylprednisolone 1g daily upfront[37]. Higher initial dose of steroids is associated with a
lower risk of MACE ((methyl)prednisolone dose: 160 mg versus 72.5 mg; p=0.055)[12]. In
our series, prompt initiation of high-dose corticosteroids rapidly normalised cardiac enzyme
in three out of five patients (Figure 2). Case two and three received methylprednisolone 1g
daily upfront in part because of their higher initial hs-TnT. Some patients required the
addition of mycophenolate and IVIg in the setting of persistent troponin elevation.
Antithymocyte globulin, IVIg, and infliximab have been used in steroid refractory cases of
myocarditis, although infliximab is not preferred at higher dosing given its association with
cardiac failure[12, 15, 38]. Tacrolimus and ciclosporin could be considered in refractory

A Closer Look at Immune-Mediated Myocarditis
cases given their efficacy in treating allograft rejection[39]. Importantly, high-dose immunosuppression must be weighed against the risk of reversing desired anti-tumour immunity. In this series, three of the four responders maintained partial or complete metabolic responses. One patient had stable disease at the time of myocarditis diagnosis, but developed tumour progression 4.6 months later. Another patient never responded to ICI.

The long-term sequelae of immune-mediated myocarditis is yet to be characterised. In a retrospective case series patients with immune-mediated myocarditis, an elevated discharge troponin T (> 1.5 ng/ml) was associated with a 4-fold increased risk of MACE suggesting prolonged low-grade inflammation is detrimental[12]. There is currently no evidence to guide the need for cardiac monitoring, optimal follow-up strategy, or the role of cardioprotective therapies in patients with persistently myocardial inflammation due to ICI and/or TKI.

**CONCLUSION**

We highlight the challenges in the diagnosis and management of immune-mediated myocarditis. CMRI and FDG-PET are useful diagnostic tools that warrant further evaluation. Immune-mediated myocarditis is an important clinical event requiring prompt diagnosis and multidisciplinary management. Future clinical trials combining ICI and TKI need to prospectively collect biomarkers of toxicity to facilitate the mechanistic dissection of this serious side effect.

TTE 18 months after myocarditis onset
LVEF: 51%.

ACE, angiotensin converting enzyme; BD, twice daily; CK, creatine kinase; CMR, complete metabolic response; CMRI, cardiac magnetic resonance imaging; ECG, electrocardiogram; hs-TnT, highly-sensitive cardiac troponin T; IV, intravenous; LGE, late gadolinium enhancement; LVEF, left ventricular ejection fraction; NA, not available; OD, once daily; PMR, partial metabolic response; CMR, complete metabolic response; PO, per oral; TTE, transthoracic echocardiogram.
**Patient 1**
- MP 2 mg/kg
- Prednisolone 2 mg/kg then wean

**Patient 2**
- MP 1 mg/kg
- Prednisolone 1 mg/kg then wean

**Patient 3**
- MP 1g
- Prednisolone 2 mg/kg then wean
- Mycophenolate mofetil (1.5g BD)

**Patient 4**
- ACS management
- Prednisolone 2 mg/kg then wean
- Mycophenolate mofetil 1g BD
- IVIg

**Patient 5**
- Prednisolone 2 mg/kg then wean

Units: ng/L (hs-TnT) or U/L (CK)
FIGURE LEGENDS

Fig. 1. Characteristic cardiac MRI findings of immune-mediated myocarditis. A. Post-contrast image: four chamber showing normal black myocardium with area of bright late gadolinium enhancement (arrows) in the anterolateral wall sparing the subendocardium, consistent with necrosis or scarring due to myocarditis. B. Post contrast image: short axis image of left ventricle showing mid-wall late gadolinium enhancement (arrows) consistent with necrosis or scarring due to myocarditis. C. T2 weighted (STIR) image: left ventricle in short axis showing mid-wall high signal (arrows) indicative of myocardial oedema.

Fig. 2. Cardiac enzyme levels in correlation with treatment in patients with immune-mediated myocarditis. Each panel provides the CK (grey) and hs-TnT (black) levels for each patient from the time of myocarditis diagnosis. Black horizontal arrows represent the timing of immunosuppressive therapies. Black vertical arrows under the letters MP or IVIg represent each dose administered. Patient 4 developed myositis which was diagnosed on day 72. MP, methylprednisolone; ACS, acute coronary syndrome; IVIg, intravenous immunoglobulin.
