Keywords: thermo-cells, body heat, gel electrolyte, electrode/electrolyte integration

Abstract: Thermo-electrochemical cells (thermo-cells) designed for harvesting human body heat can provide a constant power output for wearable electronics, supplementing state-of-the-art flexible power storage and conversion solutions. However, a systematic investigation into the optimization of wearable thermo-cells is lacking, especially with regard to device design, n-type electrolytes, and electrode/electrolyte integration. Here, a n-type gel electrolyte: polyvinyl alcohol (PVA)-FeCl$_{2/3}$ with outstanding flexibility and elasticity is produced, which demonstrates exceptional electrolyte/electrode integration into a 3D porous poly(3,4-ethylenedioxythiophene)/polystyrenesulfonate (PEDOT/PSS) electrode via an in-situ chemical crosslinking method. The integrated n-type cell shows excellent seebeck coefficients (0.85 mV K$^{-1}$) and output current density (1.74 A m$^{-2}$ K$^{-1}$) that are comparable with an optimized p-type cell consisting of a carboxymethylcellulose (CMC)-K$_{3/4}$Fe(CN)$_6$ electrolyte with a 3D PEDOT/PSS-edge functionalized graphene/carbon nanotube(PEDOT/PSS-EFG/CNT) electrode (-1.22 mV K$^{-1}$ and 1.85 A m$^{-2}$ K$^{-1}$). The equivalent performance of the n-type and p-type cells enables the effective series connection of up to 18 pairs of p-n cells that combines to give an output voltage of 0.34 V ($\Delta T = 10$ °C).
This in-series device is fabricated into a proof-of-concept watch strap, which can harvest body heat, charge supercapacitor (up to 470 mF) as well as illuminate a green LED, clearly demonstrating the practical application.

1. Introduction

The emergence of wearable electronic devices has stimulated the demand for a flexible, light-weight and high-efficiency power supply system.\[^{1,2}\] In contrast to more traditional energy storage systems (e.g. batteries\[^{3}\] and supercapacitors\[^{4}\]), which require manual recharging, flexible energy harvesters (including solar cells\[^{5}\], piezoelectric polymer generators\[^{6,7}\], triboelectric generators\[^{8,9}\] and thermoelectric generators\[^{10-13}\]) convert energy from the local environment, including mechanical motion or temperature gradients from the human body, to electrical charge.\[^{14,15}\] These energy harvesters are environmentally friendly power sources, which potentially provide a pathway towards the elimination of manual device charging and a reduction in battery waste.\[^{10}\] Among these power sources, thermoelectric generators (TEG) attached to the human body are highly attractive, as the heat continually being emitted by the body (up to 20 mW/cm\(^2\)) enables a constant power supply, in contrast to motion-based, or solar-based energy harvesting technologies.\[^{10-13,16,17}\] We have recently discussed the promising prospect of body heat harvesting in the future global market of wearable electronics and provided possible designs for a skin-conformal TEG.\[^{10}\] However, relatively low figures of merit (such as the Seebeck coefficient, \(S_e = \Delta V/\Delta T\), which is typically on the order of \(\mu V K^{-1}\))\[^{18}\] and the reliance on rigid and expensive thermoelectric materials have greatly limited the practical development of TEGs for wearable applications.\[^{10}\] Thermo-electrochemical cells (thermo-cells, TECs) harvest thermal energy through the temperature-dependent electron transfer between redox couples and electrodes, and typically exhibit much higher Seebeck coefficients (on the order
of mV K$^{-1}$) than TEGs.$^{[18]}$ Thermo-cells have a simple structure and can be fabricated from inexpensive materials, making them ideal candidates for low-grade heat harvesting (e.g. body heat) for wearable technologies.$^{[18-20]}$ Thermo-cells are also extremely attractive as they can constantly generate energy, provided there is a suitable thermal gradient, without any toxic emissions or chemical waste.

Great progress has been made in flexible and wearable thermo-cells, however, this progress has focused on two main aspects: flexible electrodes$^{[20-22]}$ and leak-free gel electrolytes.$^{[23-25]}$ To prepare flexible electrodes, inexpensive carbon-based materials or conducting polymers are often used instead of traditional and expensive platinum electrodes. The first report of flexible electrodes for wearable TECs used an activated carbon textile (ACT) coated with carbon nanotubes (CNTs).$^{[20]}$ Further investigations built on this platform using free-standing carbon-based materials (e.g. graphene/CNT films,$^{[21,26]}$ MWNT foam,$^{[22,27]}$ activated carbon cloth,$^{[22]}$ CNT/PtNPs aerogel$^{[27]}$ and others) and confirmed that higher surface areas, electrocatalytic behavior, enhanced porosity, and improved electrical conductivity are key considerations to achieve substantial advances in thermo-cell performance. In addition, the charge carrier electrolyte has been the subject of intensive development, with a focus on the development of gel electrolytes with no solvent leakage for wearable application.$^{[28]}$ In gel electrolytes, the selection of a suitable polymer for the redox active species plays the most important role. The polymer needs to provide a mechanical matrix sufficient to prevent solvent leakage but also have a high diffusion coefficient (on the order of $10^{-5}$ cm$^2$ s$^{-1}$) of redox couples to enable sufficient transport. For the $[\text{Fe(CN)}_6]^{3/4-}$ redox system, various water-soluble polymers (agar agar,$^{[23]}$ gelatin,$^{[23]}$ poly(sodium acrylate),$^{[23]}$ polyvinyl alcohol$^{[19,24]}$ and celluloses$^{[24]}$) have been explored, where gelation was induced by cooling down a hot mixture.
containing $[\text{Fe(CN)}_6]^{3-/4-}$ and a polymer. Polyanions with carboxyl functional groups, including poly(sodium acrylate)$^{[23]}$ and carboxymethylcellulose (CMC)$^{[24]}$ are able to form gels containing high concentrations of $[\text{Fe(CN)}_6]^{3-/4-}$ (as high as 0.4 M). In addition, superabsorbent polymer hydrogels (like polyacrylamide)$^{[24]}$ or polymer films (e.g. cellulose)$^{[25]}$ can also be immersed in the aqueous redox electrolyte and produce a gel electrolyte. Optimizing the weight percentage of the polymer is crucial to balance the mechanical properties and enable fast ion transport. However, all previous reports are independent studies on either the electrode or the electrolyte. There have been no reports of a system where advanced electrodes are coupled to new, optimized, gel electrolytes; this is crucial as the interfacial properties, specifically wettability and charge transport phenomena, vary dramatically between traditional metal and the advanced carbon-based electrodes.

To date, developments in thermo-cells have focused on optimization for individual cells. However, with appropriate design considerations, single cells with alternating negative and positive Seebeck coefficients can be coupled in series to form an array that improves the overall output voltage for practical applications (Figure 1)$^{[19,29,30]}$. These arrays of thermo-cells are analogous to the $p$- and $n$-doped TEGs, and therefore denoted as $p$-type and $n$-type thermo-cells in this manuscript. The output current of $p-n$ cells connected in series (denoted as $p-n$ cells) is limited by the lowest current of the individual single cells, so it is of vital importance to match the current output for both $p$-type and $n$-type half-cells for efficient and optimal performance.$^{[30]}$ It is noted that most of the literature on TECs is focused on the development of $p$-type electrolytes (where the absolute charge of the oxidant is smaller than the reductant), often based on $[\text{Fe(CN)}_6]^{3-/4-}$, with only a few reports focused on fabrication of $n$-type gel electrolytes (where the absolute charge of the oxidant is larger than the reductant)$^{[18,30]}$. The performance of $n$-type cells with either aqueous$^{[31,32]}$ or gelled
electrolytes are intrinsically lower than p-type cells in terms of current due to sluggish kinetics. For example, Aldous et al. investigated the fundamentals of combining the conventional [Fe(CN)]$_6^{3-/4-}$ p-type thermo-cell with Fe(II/III) sulfate as an n-type thermo-cell, both electrically in-series and in-parallel. Zhou et al. mixed polyvinyl alcohol with FeCl$_{2/3}$ as an n-type thermo-cell, and coupled it with a 0.02 M [Fe(CN)$_6$]$^{3-/4-}$ redox couple as a p-type cell. Kimizuka et al. prepared a polysaccharide/I$^-$/I$_3$ n-type gel electrolyte and improved the Seebeck coefficient from +0.86 to +1.5 mV K$^{-1}$ by introducing polymer-ion interactions. Pringle et al. prepared the first aqueous gel electrolyte based on a cobalt redox couple, Co(bpy)$_3$Cl$_{2/3}$, using a cellulose film as the polymer matrix, which exhibits a Seebeck coefficient of +1.21 mV K$^{-1}$. Despite these efforts, the best reported output current and power for n-type cells is still one order of magnitude lower than the p-type cells. In addition to the electrolyte, flexible electrodes which can catalyze the redox reaction of n-type couples has not been well studied in detail to date. Therefore, the study on the n-type cells in terms of both the electrode and gel electrolyte is a key challenge to develop effective p-n cells and produce efficient integrated arrays of p-n cells.

In this work, we systematically investigated the performance of both p-type and n-type thermocells through study and optimization of both the flexible electrode and gel electrolyte, enabling the development of high performance p-n cell arrays for practical body-heat energy harvesting applications (as illustrated in Figure 1). Firstly, to address the relatively low performance of n-type devices, we systematically prepared a flexible and stretchable n-type gel electrolyte (PVA-FeCl$_{2/3}$). This PVA-FeCl$_{2/3}$ electrolyte can accommodate a wide range of FeCl$_{2/3}$ concentrations (0.1 M to 2 M) without affecting the gelation process and maintaining the thermo-electrochemical performance of the Fe$^{2+}$/Fe$^{3+}$ redox couple. This n-type gel electrolyte demonstrated comparable performance with
the previously developed p-type electrolyte of carboxymethyl cellulose (CMC)-K$_{3/4}$Fe(CN)$_6$ with Pt electrodes.\textsuperscript{[24]} The performance of both p-type and n-type cells was optimized using 3D structured poly(3,4-ethylenedioxythiophene)/polystyrenesulfonate-edge functionalised graphene/carbon nanotubes (PEDOT/PSS-EFG/CNT) and PEDOT/PSS film electrodes, respectively. A pair of p-type and n-type TECs (p-n cells) with comparable output current were coupled to achieve a power density equal to the sum of p- and n-type half-cells, indicating the low internal resistance of electrode materials. We then demonstrated the scalability of the system, fabricating an array with 18 pairs of p-n series devices able to charge capacitors to above 0.3 V. Finally, we prototyped the p-n array into a watch-strap-style integrated device, which efficiently converted body heat to electrical energy and provided continuous power to a green light emitting diode (LED).

2. Results and Discussions

2.1. Developing an n-type gel electrolyte

An n-type PVA-FeCl$_{2/3}$ gel electrolyte was prepared by chemically cross-linking PVA in the presence of FeCl$_{2/3}$. To achieve gel formation, 1 M FeCl$_{2/3}$ was dissolved in 5 wt.% PVA (85 – 124 kDa) in H$_2$O, forming a relatively low-viscosity solution. Glutaraldehyde (GA) diluted solution (5 wt.%) was then added, accompanied by rapid and vigorous stirring. The mixed solution was immediately poured into a mould or injected into the thermo-electrochemical cell. In the weakly acidic Fe$^{2+}$/Fe$^{3+}$ solution, the cross-linked PVA hydrogel was formed \textit{via} the reaction between the hydroxyl groups of PVA and the aldehyde groups in GA (forming acetal or hemiacetal links between PVA polymer chain).\textsuperscript{[35]} After 0.5 hour, the cross-linked gel electrolyte was able to be removed from the mould (for physical characterization) or directly used as an electrolyte in thermo-cells.
The as-prepared n-type gel electrolyte is highly flexible and stretchable (Figure 2a), and can maintain its shape after being bent, twisted, or even stretched to twice its original length while being twisted over 360 degrees. After repeated cyclic stretching to 100% strain (Figure 2b), the gel electrolyte shows less than 10% plastic deformation (over 60 cycles), indicating its excellent elasticity and cyclic stability. These robust mechanical properties (flexibility, elasticity, and toughness) emphasizes the potential of this gel electrolyte in wearable applications and even epidermal devices. Meanwhile, this gel electrolyte could be potentially adapted to fit future stretchable thermo-cells, which is not the subject of this work but merit considerable further study for wearable devices. The effect of the molecular weight and concentration of PVA, as well as the concentration of FeCl$_{2/3}$ and acidity of the electrolyte were investigated to achieve optimal parameters with respect to mechanical properties, ionic conductivity, and thermo-cell performance (See Supplementary Information text, Figure S1-S5). Meanwhile, extended thermo-electrochemical performance over 4 days were test to show the excellent thermo-electrochemical stability of the gel electrolyte (See Supplementary Information text, Figure S5d). Below we discuss the performance of the optimized n-type gel electrolyte.

The electrochemistry of the as-prepared PVA-FeCl$_{2/3}$ gel electrolyte (5 wt.% PVA and 1 M FeCl$_{2/3}$ concentration) was evaluated and compared to a 1 M FeCl$_{2/3}$ aqueous electrolyte (Figure 2c-d) using a thin-film platinum electrode (ED-SE1-Pt, Micrux) where Pt works as both the reference and counter electrodes. The gel electrolyte displayed an almost identical cyclic voltammetry (CV) curve (scan rate = 50 mV s$^{-1}$) to the liquid electrolyte, with a slightly smaller separation between the reduction and oxidation peaks ($\Delta E_p$) (216 mV vs. 257 mV). The $\Delta E_p$ relates to the reversibility of the redox couples in gel and liquid electrolyte, indicating that the electro-activity of redox couples has not been affected.
by the presence of the PVA polymer host. The same diffusion limited redox behavior was observed in both gel and liquid electrolytes, reflected by the linear relationship between the square root of scan rate and the peak current density (Figure S1d and Figure S2d).\(^{(23,38)}\) The high frequency domain of electrochemical impedance spectra (EIS) of both gel and liquid electrolytes shows a small equivalent series resistance (ESR) (50 Ω, derived from the intercept of the real part of impedance with the x-axis), indicating that the gel electrolyte exhibits a comparably high ionic conductivity to the liquid electrolyte.\(^{(36,39)}\) As expected, a larger electron transfer resistance (R\(_{\text{ET}}\), defined by the size of the semicircle at high frequency domain) was observed in the gel polymer electrolyte (90 Ω) than in the liquid electrolyte (50 Ω).\(^{(36,39)}\) However, this charge transfer resistance was still small enough to enable rapid charge transport and enable rapid redox reactions, as evidenced by the CV results. Therefore, the redox reaction of the as-prepared PVA-FeCl\(_{2/3}\) gel electrolyte is quasi-reversible and displays similar electrochemical performance compared with the liquid electrolyte.\(^{(38)}\)

Given the promising CV and EIS results, the thermo-electrochemical (TEC) performance of these gel electrolytes was further investigated. As discussed in the experimental section, sputter-coated platinum was used for the electrodes with a 2 mm inter-electrode spacing. While maintaining the temperature of the hot electrode (T\(_H\)) at 35 °C and gradually decreasing the cold electrode temperature (T\(_C\)) from 30 °C to 15 °C, the output voltage was observed to change linearly with ΔT (Figure S3), giving a Seebeck coefficient of +0.78 mV K\(^{-1}\). The Seebeck coefficient was slightly smaller compared to that of an aqueous electrolyte system (+0.81 mV K\(^{-1}\)). This difference is hypothesized to arise from the higher thermal conductivity of cross-linked polymer gels (PVA-FeCl\(_{2/3}\) gel: 1.02 W m\(^{-1}\) K\(^{-1}\), PVA gel: 1.01 W m\(^{-1}\) K\(^{-1}\)) compared to water-based systems (PVA aqueous solution: 0.588 W m\(^{-1}\) K\(^{-1}\), water: 0.60 W m\(^{-1}\) K\(^{-1}\)), the value of PVA-FeCl\(_{2/3}\) solution and FeCl\(_{2/3}\) aqueous solution were not
measured to avoid the corrosion of the metal thermal sensor by acidic solution). Since the use of chemical cross-linking clearly demonstrates significant advantages such as strong mechanical strength and high concentration of redox couples, the slight decrease in Seebeck coefficient is acceptable. The TEC shows a simple linear current - voltage and parabolic power - voltage relationship, with a short circuit current density ($J_{SC}$) of 8.2 A m$^{-2}$ and maximum power density ($P_{MAX}$) of 17.1 mW m$^{-2}$ (Figure 2e). The smaller $J_{SC}$ (8.2 A m$^{-2}$) of the gel electrolyte compared to the liquid electrolyte (12 A m$^{-2}$) arises from the lower $R_{CT}$ (Figure 2d). The result shows the n-type electrolyte performance is comparable to reported p-type electrolytes when sputter-coated Pt was used as electrode (Figure S6), demonstrating the potential for development of p-n arrays.

2.2. Electrode optimization for p- and n- type cells

Once the electrolyte had been fully optimized, development of advanced electrodes tailored to match our gel electrolytes was undertaken to achieve the maximum possible device performance. To enable intimate contact between the electrode materials and the flexible substrate, a simple drop-casting method was used to prepare electrodes on Pt-coated PI tape (Figure 3a). This method eliminates the need for any additional steps to transfer the free-standing electrodes onto the target substrate. For a homogenous drop-casting dispersion, a water-dispersible and commercially available conducting polymer PEDOT/PSS was used as a dispersing agent for carbon-based materials (i.e. EFG and CNTs). Uniform PEDOT/PSS-EFG/CNT dispersions could be formed when the ratio of PEDOT/PSS was larger than 25 wt.% in the composite. Diethylene glycol (DEG), which is a commonly employed secondary dopant for PEDOT/PSS used to boost the electrical conductivity, was added to all samples. In addition, a thin layer of PEDOT/PSS (0.3 mg cm$^{-2}$) was prepared as a soft and adhesive layer on the flexible substrate, prior to the PEDOT/PSS-EFG/CNT film drop-casting process.
This additional layer serves to prevent delamination of the composite film from the substrate during the heat evaporation process (Figure S8) or during bending (Figure 3a). A CO₂ laser cutter was used to etch the electrode materials creating ≈ 100 μm wide channels (Figure S7) with a depth equal to the thickness of the film electrode. This process was used to increase the surface area and increase diffusion of the redox species through the electrode films. The as-prepared electrodes (Figure 3a, b) on PI tape were assembled into a TEC device, followed by injection of the gel electrolyte (p-type: CMC-K₃/₄Fe(CN)₆, n-type: PVA-FeCl₂/₃, respectively) into the device. TEC performance of the film electrodes and the full TEC device was evaluated while applying a ΔT = 10 °C between the two electrodes (T_H = 35 °C and T_C = 25 °C). Step-by-step optimization of the electrode composition and film thickness (See Supplementary Information text and Figure S9 and Figure S10) was performed to attain high performance electrodes.

Figure 3c shows the optimized performance of the p-type electrode (laser-etched PEDOT/PSS-EFG/CNT), which has improved thermo-electrochemical performance compared with the PEDOT/PSS-EFG/CNT film and pristine platinum electrodes in terms of open circuit voltage (12.2 mV versus 11.5 mV and 10.2 mV, demonstrating an improvement in ‘observed ΔT’), short circuit current density (18.5 A m⁻² versus 19.5 A m⁻² and 10.2 A m⁻²), and maximum power density (72.9 mW m⁻² versus 60.7 mW m⁻² and 32.9 mW m⁻²) at ΔT = 10 °C. A high P_MAX/ΔT² value of 0.73 mW K⁻² m⁻² (comparable to literature values for high-performance electrodes)²² was calculated to account for the difference in ΔT of thermo-cells run at different operating temperatures. We ascribe the improved performance to the high-quality EFG, the open and porous layer-by-layer structure (Figure 3b), and the laser-etched channels enabling a high ion-accessible surface area with high electrical conductivity. The optimal p-type electrode composition of PEDOT/PSS-EFG/CNT film electrode
outperforms all others in terms of current density and power density. This performance arises due to the synergistic combination of EFG and CNTs, which form a hierarchically porous, high surface area network with outstanding electrical conductivity and known electrocatalytic behavior for the \([\text{Fe(CN)}_6]^{3-/4-}\) redox couple.\(^{18,21,42-44}\) However, the thick PEDOT/PSS-EFG/CNT film electrode also exhibits increased thermal resistance, resulting in a relatively low open circuit voltage of 10.2 mV. To solve this problem, the additional laser-etching process was applied to the film electrode, which enabled the direct exposure of thermally conductive Pt to the gel polymer electrolyte. The key benefit of this additional process was that the effective temperature difference between the cold and hot electrode/electrolyte interface was increased, leading to an enhancement in the open circuit voltage compared with the un-etched samples (from 10.2 mV to 12.2 mV) without sacrificing the output current. An improved \(P_{\text{MAX}}\) was thus achieved from 60.7 mW m\(^{-2}\) to 72.9 mW m\(^{-2}\).

In terms of the long-term power output of the optimized device, the short circuit current (\(I_{\text{SC}}\)) over time was measured (Figure S11a) and the long-term \(P_{\text{MAX}}/\Delta T^2\) (\(P_{\text{MAX}}=1/4 \times I_{\text{SC}} \times V_{\text{OCV}}\)) was calculated. The high current output and \(P_{\text{MAX}}/\Delta T^2\) decreased initially before stabilizing after 30 min of thermo-cell discharge. This decrease is a limitation of all gel-related thermo-cells and arises from the low diffusion rate of redox couples in gel electrolyte. Due to the higher driving potential for ion diffusion, the laser-etched PEDOT/PSS-EFG/CNT maintains a higher long-term current density (1.15 A m\(^{-2}\) \textit{versus} 1.0 A m\(^{-2}\)) and \(P_{\text{MAX}}/\Delta T^2\) (0.0351 mW K\(^{-2}\) m\(^{-2}\) \textit{versus} 0.0255 mW K\(^{-2}\) m\(^{-2}\)) compared to an unetched electrode. The 38% improvement in \(P_{\text{MAX}}/\Delta T^2\) indicates the efficacy of the laser-etching process. The long-term \(P_{\text{MAX}}/\Delta T^2\) of our optimized device is comparable with reported gel electrolyte systems.\(^{19,23,25,45}\)
Once the p-type cell electrode was optimized, electrodes suitable for use with our developed PVA-FeCl_{2/3} electrolytes (n-type) were investigated, with a target of reaching comparable performance to the p-type configuration. Surprisingly, it was found that the single component film electrode of PEDOT/PSS exhibited superior performance surpassing all the other studied carbon-based materials including PEDOT/PSS-EFG, PEDOT/PSS-CNT, and PEDOT/PSS-EFG/CNT (Figure S10a). This outstanding performance may have arisen from the unique electrocatalytic behavior of PEDOT/PSS for the Fe^{2+}/Fe^{3+} redox couple. As reported in the literature, excess PSS in PEDOT/PSS can enhance cation transport through the polymer electrode with a particularly high affinity for multivalent cations such as Fe^{2+} and Fe^{3+}. Due to their strong electrostatic attractions, Fe^{2+} and Fe^{3+} ions can easily absorb onto the electrode surface of PEDOT/PSS film electrodes.\[^{46,47}\] Along with the high electrical conductivity and abundant micro-sized pores in the electrode film (Figure 3d), fast ion diffusion and electron transfer are predicted in the PEDOT/PSS electrodes.\[^{41}\] The performance of PEDOT/PSS was further improved by increasing the mass loading to 4 mg cm^{-2} (Figure S10b) and adding an additional laser-etching (Figure 3e) process for enhanced output current and output voltage. A full summary of the tested electrodes and their relative performance is shown in Table S1.

After optimization, the laser-etched PEDOT/PSS electrodes delivered a much higher TEC performance than PEDOT/PSS film and pure Pt electrodes (Figure 3e), including the open circuit voltage (8.9 mV versus 6.7 mV and 8.0 mV), short circuit current density (17.4 A m^{-2} versus 14.4 A m^{-2} and 10.2 A m^{-2}), and maximum power density (38.3 mW m^{-2} versus 24.3 mW m^{-2} and 20.6 mW m^{-2}). Notably, this is the first time that the performance of an n-type device has been optimized in combination with conducting polymer-based electrode materials, which exhibit comparable performance with carbon-based materials in aqueous electrolyte.\[^{31,48}\] In addition, the ease in...
dispersion preparation and the processability of PEDOT/PSS has greatly simplified the film preparation process compared to the alternative carbon-based electrodes.\(^{31,48}\) In terms of long-term performance, the laser-etched process shows the same benefit in n-type devices as in p-type device (Figure S11b). There is a 25\% improvement in current density (1.5 A m\(^{-2}\) versus 1.2 A m\(^{-2}\)) and 60\% increase in \(P_{\text{MAX}}/\Delta T^2\) (0.0322 mW K\(^{-2}\) m\(^{-2}\) versus 0.0201 mW K\(^{-2}\) m\(^{-2}\)) when comparing the laser-etched PEDOT/PSS device to the unetched device. The long-term \(P_{\text{MAX}}/\Delta T^2\) is also comparable with the literature-reported gel electrolytes.\(^{19,34,49}\) In addition, it is found that the output current of this optimized n-type device is comparable with our optimized p-type device in terms of both the initial value (17.5 A m\(^{-2}\) versus 18.5 A m\(^{-2}\)) and the long-term value (1.5 A m\(^{-2}\) versus 1.15 A m\(^{-2}\)), indicating the potential for effective p-n in-series connection.

2.3. Pairing the p-n cells

As mentioned above, the selection criteria for efficient series connection between p-type and n-type cells is the comparable output current between each device, which has been achieved herein via the optimization of both electrolyte and electrode for both p-type and n-type devices. Here, a typical pair of p-n cells were fabricated and examined (Figure 4a), where the optimized electrodes of laser-etched PEDOT/PSS and PEDOT/PSS-EFG/CNT and electrolytes of PVA-FeCl\(_2/3\) (1 M FeCl\(_2/3\)) / 0.08 M HCl and CMC-K\(_{3/4}\)Fe(CN)\(_6\) [0.4 M K\(_{3/4}\)Fe(CN)\(_6\)] were used in n-type and p-type cells, respectively. Sputter-coated Pt acts both as the current collector and the connection between adjacent devices. As expected, the voltage of the p-n combined cell was approximately equal to the sum of the absolute voltage of both p-type and n-type devices, and increased linearly with \(\Delta T\) (Figure 4b). Thus, the effective Seebeck coefficient of the p-n cell was 1.96 mV K\(^{-1}\), approaching the sum of the absolute value of each component (-1.17 mV K\(^{-1}\) for p-type device, and +0.85 mV K\(^{-1}\) for n-type
device). Further, the initial and the long-term short-circuit current of the p-n cell was nearly the same as the individual p-type and n-type devices at a $\Delta T = 10$ K, indicating the efficient matching and low resistance of the electrical connections between the devices (Figure 4b and Figure S11c). The p-n cell performance at various $\Delta T$ (5~20 K) was examined, yielding linear $V$ vs $I$ and parabolic $P$ vs $V$ relationships at all temperature differences. These results indicate that the p-n cell was stable at a variety of temperatures.

2.4. Prototyping multiple p-n cells

A prototype device of thermo-cell arrays containing multiple p-n cells connected in series was fabricated (6 pairs of p-n cells in Figure 5a, and $3 \times 6$ pairs of p-n cells in Figure 5b) and the scalability (with respect to the number of p-n units in the device) was probed. With a $\Delta T$ of 10 K, the voltage increases linearly from 20.1 mV to 351 mV with increasing number of p-n cell pairs from 1 to 18. We also note that the current output (blue curve, Figure 5c) decreased when the number of p-n pairs increased due to an increasing amount of electrical resistance between cell connections. As a result, the power output reaches a plateau when there are 18 pairs of p-n cells. Due to the high energy output (up to 38.3 $\mu$W) from the 18 pair configuration, the p-n cell arrays ($\Delta T = 10$ K) were able to charge not only a capacitance dielectric capacitor ($C = 10 \text{ mF}$), but also electrochemical supercapacitors ($C = 47 \text{ mF}, 100 \text{ mF}, 470 \text{ mF}$) to more than 300 mV. The charge rate for 10 mF, 47 mF and 100 mF supercapacitors is high and charging could be achieved in a few minutes. One problem with using the gel electrolytes in-series is the decrease in long-term performance, which resulted in a decrease in the charging rate of supercapacitors after extended durations, especially for supercapacitors with large capacitances (i.e. 470 mF). This limitation of long-term performance is expected to be solved in the future when advanced gel electrolytes are developed, leading to greatly
improved long-term charging rates with our advanced electrode and p-n series system. In addition, we also claim that this is the first time that thermo-cells with gel electrolyte harvesting low-grade heat have been demonstrated to charge high energy density supercapacitors, and subsequently power a LED.

2.5. Flexible and wearable p-n cells

To harvest body heat, a flexible thermo-cell, which can conform to a curved surface is required. However, bending layered devices to a high degree of curvature while maintaining performance is challenging, even when the individual components are highly flexible, as the top electrodes (air-side) always bear larger deformation relative to the bottom electrodes (skin-side). To address this problem, we designed a thermo-cell with a watch-strap shape, where the bottom electrodes between p-n cells were electrically connected on one flexible substrate (i.e. polyimide tape) but the top electrodes were not connected and separated on different substrates (Figure 6a). In this case, the top electrodes of each p-n pair could move freely, while the bottom electrodes conformed to the high curvature encountered with anatomical parts. Meanwhile, flexible and thermally conductive aluminum foil was attached outside of the thermo-cell device in order to maintain uniform heat transfer through electrodes. As a demonstration, we have attached 5 straps of thermo-cell arrays (6 p-n pairs) on a wrist (Figure 6b). These 30 p-n pairs can charge a 470 mF supercapacitor during long-term wear. The charged supercapacitor was able to light a green LED with voltage booster (Figure 6b and Supporting Information Movie S1). This demonstrates the practical utility of our thermo-cells to power a range of wearable and portable electronics from low-grade body heat.

3. Conclusion
In summary, we have developed high performance p-type and n-type flexible thermo-cells through systematic investigation of both electrodes and gel electrolytes, which are of vital importance in establishing effectively paired p-n cells. We have shown that an optimized n-type PVA-FeCl$_{2/3}$ gel electrolyte prepared by an in situ chemical cross-linking exhibits comparable performance to the state-of-the-art p-type electrolyte [CMC-K$_{3/4}$Fe(CN)$_6$]. Then, we developed and optimized both p-type and n-type electrodes with a flexible and porous structure. PEDOT/PSS and PEDOT/PSS-EFG/CNT electrodes showed excellent and comparable performance for n-type and p-type cells respectively, enabling the devices to be coupled together efficiently. We also successfully matched these thermocells by connecting multiple p-n cells in series, achieving an increased voltage to 0.34 V at $\Delta T = 10$ K and a current large enough to charge supercapacitors. Furthermore, the demonstration of a flexible watch-strap shaped thermo-cell that could harvest body heat, charge supercapacitors and light a green LED, highlighted the potential of these devices in real applications. We believe this systematic investigation and optimization of electrode, electrolyte, and device architectures introduced here has great significance for the realization of body heat harvesting and application in real self-powered wearable electronics.

4. Experimental Section

Materials: The PEDOT/PSS used was the Orgacon™ DRY product from Agfa Company. Multi wall carbon nanotubes (MWCNT) were obtained from Carbon Nanotube Plus. Edge functionalized graphene (EFG) was prepared in our laboratories.$^{[50]}$ Diethylene glycol (DEG), polyvinyl alcohol (PVA, Mw: 31,000 - 50,000, 83,000 - 124,000, 146,000 - 186,000 Sigma 363162), carboxymethylcellulose sodium (CMC, Mw: 250,000), iron (II) chloride tetrahydrate (FeCl$_2$·4H$_2$O), iron (III)...
chloride (FeCl₃), potassium ferricyanide [K₃Fe(CN)₆], potassium hexacyanoferrate (II) [K₄Fe(CN)₅·3H₂O], glutaraldehyde solution (25 wt.% in H₂O) were purchased from Sigma-Aldrich.

**PVA-FeCl₂/₃ gel electrolyte solution:** PVA-FeCl₂/₃ solutions were prepared by dissolving FeCl₂·4H₂O and FeCl₃ powder into pre-prepared PVA aqueous solutions (with magnetic stirring) for 1 h. PVA solutions of 3 wt.%, 5 wt.%, 8 wt.% and 10 wt.% were used, with 0.1 M, 0.2 M, 0.5 M, 1 M, or 2 M FeCl₂/₃. The chemical cross-linker of diluted GA (5 wt.% in H₂O, mass ratio of PVA:GA = 40:1) was then dropped into the mixed solution with vigorous magnetic stirring for 30 s. Subsequently, the PVA-FeCl₂/₃-GA solution was immediately poured into a PDMS mould or injected into the assembled thermo-electrochemical device. Finally, the solid-state gel electrolyte was formed after cross-linking at room temperature for 1 h, which was then either peeled off for electrochemical and mechanical testing or directly used as electrolyte in the thermo-electrochemical device. For performance enhancement, HCl with the final concentration varying from 0.02 to 0.3 M was added into the PVA-FeCl₂/₃ solutions before the addition of chemical cross-linker (GA).

**CMC-K₃/₄Fe(CN)₆ gel electrolyte:** CMC-K₃/₄Fe(CN)₆ gel electrolyte was prepared following the method described by Russo et al.,[24] whereby the appropriate amount of CMC powder was added to 0.4 M K₃Fe(CN)₆/K₄Fe(CN)₆ aqueous solution with magnetic stirring overnight. The prepared viscous CMC-K₃/₄Fe(CN)₆ solution was stirred for at least 30 min prior to being injected into thermo-electrochemical devices for performance testing.

**Preparation of flexible film:** A ball milling method was used to prepare PEDOT/PSS-based inks. Firstly, PEDOT/PSS pellets with different mass loadings of MWCNT and EFG were mixed by ball milling at 1200 rpm for 10 min. This ball milling process works on the principle of impact and attrition when

the balls drop from near the top of the shell. After ball milling, the MWCNT and EFG powers are bound to the surface of PEDOT: PSS and this mixture could be well dispersed in water by magnetic stirring overnight and bath sonicating for 30 min. DEG (weight ratio of DEG: PEDOT/PSS=1:1.86) was added to the aqueous dispersion prior to stirring. The PEDOT/PSS ink was prepared by directly dispersing the PEDOT/PSS in water with the addition of DEG. PEDOT/PSS, PEDOT/PSS-EFG, PEDOT/PSS-CNT, PEDOT/PSS-EFG/CNT films were prepared by bar coating a thin layer of the mixed dispersion on Pt coated-PI tape, where the sputter coated 100 nm platinum functions as current collector. The films were dried at room temperature overnight, followed by heating in an oven at 70 °C for 2 h to fully remove DEG.

Laser-etching of film electrode: The laser-etching step was conducted using a 10.6 μm CO₂ laser cutting system (Universal PLS6MW Multi-Wavelength Laser Platform, 30 W, spot size of ≈ 25 μm) under ambient conditions. It was conducted using a vector mode with the laser power set as 0.1% and the speed fixed at 2%. The pulses per inch was set at 500.

Device Assembly of series-connected thermo-electrochemical cells: Thermo-cell devices containing a series of interconnected p-type and n-type devices were fabricated. These devices consist of a laser-cut acrylic frame (Figure 5a, with each cell size \([l \times w \times t]\) being 0.5 × 2 × 0.2 cm), drop-casted and laser-etched film electrodes on sputter coated platinum, and a PI tape substrate. Firstly, 100 nm Pt was sputter coated on PI tape substrate (fixed on aluminum plate) with designed patterns, which act as both current collector and connection wires between single devices. Then, film electrodes were selectively drop-casted on the platinum coated electrode area (0.5 × 2 cm) and laser-etched via the laser cutting system (Figure 5a). The acrylic frame was then sandwiched between two of the electrode-Pt coated PI and sealed by epoxy resin glue. Finally, electrolyte precursors were injected.
into the cells through pre-prepared holes on the frame to form interconnected thermo-cells. Flexible series-connected, thermo-cells (Figure 6) were prepared in the same precursor, but replacing the laser-cut acrylic frame with a 3D printed flexible PDMS frame. To enable the production of flexible devices, aluminium foil instead of aluminum plates was used as a thermal conductor.

**Electrochemical characterizations of polymer gel electrolyte:** The electrochemical performance of the gel electrolyte was tested using thin-film platinum electrodes (ED-SE1-Pt, Micrux) equipped with All-In-One Platform, in which the working (diameter = 1 mm), reference, and counter electrodes were screen printed platinum. 400 μL of the gel electrolyte precursor was dropped into the cell and allowed to gel for 1 h prior to testing. The CV measurements were performed using a VSP electrochemical workstation (Bio-Logic, France) and EC-Lab software. Electrochemical impedance was obtained by employing a frequency range of 1 MHz to 0.01 Hz and an AC amplitude of 10 mV at open circuit voltage.

**Thermo-electrochemical measurements:** The thermo-electrochemical performance of the gel electrolytes was tested in a thermo-cell device with a home-made temperature controller (Figure S12). The temperature controller can moderate the aluminium plate to a specific temperature by heating or cooling via a Peltier device, which was controlled by a microcontroller (TEC-1091, Meerstetter Engineering) together with the TEC Service Software. The thermo-cell consists of two electrodes (electrode materials coated on 100 nm Pt coated PI tape) and an acrylic frame (with two holes for electrolyte injection) to fix the size of the cell to 1 cm × 1 cm and distance between the two electrodes of 2 mm. The electrolyte precursor was injected into the cell and allowed to gel for 1 h prior to testing. During testing, the hot side was kept at 35 °C simulating body heat temperature, whereas the code side was varied from 15 °C to 35 °C analogous to the outside environment. The
open-circuit voltage ($V_{oc}$) and current-voltage characterization of the cells was measured using a VSP electrochemical workstation (Bio-Logic, France).

**Physical Characterizations:** Patterns of laser-cut microdevices were observed by optical microscopy (Leica DM6000 upright microscope). The cross-section morphology of drop-cast and laser-cut films was investigated from a JEOL JSM-7500FA field emission SEM with the accelerating voltage set at 5.0 kV and the emission current at 10 mA. The tensile tests of the hydrogels (length = 50 mm, width = 10 mm, and thickness = 2 mm) were carried out using Shimadzu EZ mechanical tester (Shimadzu, Kyoto, Japan) with a load of 10 N and tensile speed of 25 mm min$^{-1}$ at room temperature.

A proof-of-concept of high-performance wearable thermo-cells is made through the systematic investigation into wearable thermo-cells with regard to the development of n-type gel electrolytes, the integration of gel electrolytes into three-dimensional porous electrode, and advanced device design. The demonstration of wearable thermo-cells harvesting body heat, charging supercapacitors and illuminating LED lights, shows the potential for real application.
