There are several limitations in the data from this case series. First, as is common with case series, selection bias is possible. Second, there was no control intervention, and the study sample was small. Third, it is uncertain whether these patients would have improved without prone positioning, although the rapid change, within 1 hour, after proning is suggestive of a favorable impact. Fourth, measures of patient dyspnea or comfort after prone positioning were not collected. Fifth, to minimize the documentation burden on nursing-staff workflow, data on patient adherence to the prone-positioning recommendation beyond the first episode of proning were not collected.

Given the potential of prone positioning as a low-cost, easily implemented, and scalable intervention, particularly in low- and middle-income countries, expeditious yet thorough testing of prone positioning in patients at risk for intubation is warranted (e.g., W. Al-Hazzani and colleagues, unpublished results [clinicaltrials.gov identifier NCT 04350723], among others).

To the Editor:

Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has caused a global pandemic that continues to wreak havoc on people’s lives and livelihoods. As of June 16, 2020, the number of coronavirus disease (COVID-19) cases surpassed 8 million, and the death toll stood at more than 400,000 (1). Although the majority of the patients developed mild symptoms and eventually recovered from this disease, a significant proportion suffered from serious pneumonia and developed acute respiratory distress syndrome, septic shock, and/or multiorgan failure (2, 3). The degree of the disease severity should result from direct viral damages on epithelial surface layer and the host immune response. SARS-CoV-2 infection may trigger a dysfunctional response leading to an overproduction of cytokines (cytokine storm) and the recruitment of more immune cells into the lungs, resulting in greater damages (4). However, the immune effectors that determine or influence the severity of the disease and the reason why immune response mediates recovery in some individuals (5), but not in others, are far from clear. In this study, we addressed these issues by analyzing the blood samples of patients with COVID-19 with varying degrees of disease severity.

* R group: six males; S group: two females and four males.
† Y: sepsis; N: no sepsis.
‡ Imaging scores observed within the 6 weeks after disease onset; regression of scores from "maximum to latest" was used as an indicator of grouping.
§ Days of ventilation from the initiation to May 8, including invasive ventilation and noninvasive ventilation less than 12 h/d.
∥ D: discharged from hospital; C: continued hospitalization as of May 8.
¶ Integral average of immune effectors within 5 weeks after disease onset. Activated CD8⁺ is defined by CD38⁺HLA-DR⁺CD8⁺ T cells (n/ml blood); activated CD4⁺ is defined by CD38⁺HLA-DR⁺CD4⁺ T cells (n/ml blood); and nAbs is defined by units of neutralizing antibodies in 1 ml blood.

Definition of abbreviations: CHD = coronary heart disease; COPD = chronic obstructive pulmonary disease; COVID-19 = coronavirus disease; ECMO = extracorporeal membrane oxygenation; HBV = hepatitis B virus; nAbs = neutralizing antibodies; R = recovering group; S = severe persistence group; SOFA = Sequential Organ Failure Assessment.
and by collecting their clinical data over a period of more than 3 months. Our findings highlight the importance of T-cell immunity in COVID-19 recovery.

**Methods**

Longitudinal peripheral blood mononuclear cells from 12 patients with severe COVID-19 hospitalized at the First Affiliated Hospital, Guangzhou Medical University, (Guangzhou, China), 6 with regressing imaging scores (recovering group [R]: R1, R2, R3, R4, R5, and R6) and 6 with no improvements in imaging scores within 6 weeks after disease onset (severe persistence group [S]: S1, S2, S3, S4, S5, and S6), were analyzed (Ethics No. 202051).

The method used for scoring computed tomographic and X-ray images was similar to the previous report (6), in which one point...
was assigned to the presence of a single lesion observed in the lung. A score was marked up or down by 0.5 points when consolidation was increased or resolved, respectively. Flow cytometric analysis for T-cell immune effectors was done using a FACSriA III instrument (BD Bioscience) and analyzed with FlowJo software (Treestar). Cytokines were measured by using Cytometric Bead Array kits (BD Bioscience). Focus reduction neutralization test was performed to evaluate the levels of neutralizing antibodies (nAbs) using Vero E6 cells infected with SARS-CoV-2 and rabbit anti–SARS-CoV-2 nucleocapsid protein polyclonal antibody (Sino Biological). The foci were visualized by TrueBlue reagent and counted with an ELISPOT reader (CTL S6 Ultra).

Discussion
The key findings of this study are 1) the lung injury and inflammation effectors (syndecan-1 and IL-6) are associated with disease severity, and 2) CD8+ and CD4+ T cells play a major role in the recovery of patients with critical COVID-19 under the caveat that adequate amounts of nAbs must also be present. These are consistent with the observations made in the studies of other severe infections with emerging viruses such as Ebola and influenza A virus H7N9 (8, 9). The T-cell immunity and lung injury markers were analyzed at a relatively early stage of COVID-19 (within Day 33 after disease onset). The updated fact that 6/6 of the R group had long been discharged while 5/6 of S group still suffered acute respiratory distress syndrome and had a prolonged use of ventilators in ICU (Table 1) strongly suggests that T-cell immunity can be used as a prognostic marker for COVID-19. Nevertheless, because of the small sample size, our findings warrant further verifications with larger cohorts.

Importantly, our study emphasizes that a balance between T-cell immunity and neutralizing antibodies is required for the COVID-19 recovery. The variability of T-cell immunity in individuals suggests that patients with a different balance of immune activation may require tailored treatments. For example, convalescent serum antibody therapy may benefit those patients who have strong T-cell immunity but low levels of nAbs (as in the case of S6), whereas other patients with insufficient T-cell activation may need a T-cell immunity boost strategy and should be cautiously treated with corticosteroids to suppress the cytokine storm.

Measurement of Short-Chain Fatty Acids in Respiratory Samples: Keep Your Assay above the Water Line

To the Editor:

Short-chain fatty acids (SCFAs) are bacterial products that have important biological functions, including maintenance of immune homeostasis (1). Growing evidence indicates that bacteria residing in the airways of patients with numerous pulmonary diseases as well as in those of healthy individuals (2, 3) are capable of making SCFAs (4). Therefore, there is growing interest in measuring respiratory SCFA concentrations because they could provide insight into biological processes in the lungs.

Sampling the lungs is challenging; the most common biospecimen is BAL fluid, which requires bronchoscopy under sedation. This invasive procedure is labor intensive and costly, and it may not be feasible in unstable critically ill patients. Exhaled breath condensate (EBC) is an easily acquired, abundant material at https://doi.org/10.7302/wk4r-7x52. Methyl tert-butyl ether (MTBE) was used for liquid extraction of SCFAs from EBC. Negative control samples, including MTBE alone, MTBE used to extract acidified water and internal standards, a water wash of the EBC acquisition equipment, and a representative sample of normal saline acquired from the bronchoscopy suite were also assayed. A postmortem porcine portal vein plasma sample was assayed as a positive control.

Data analysis. The SCFA concentrations for each subject were summed, and Pearson correlation was used to assess the association between the total SCFA concentration and the microbiome signal within each medium. The summed SCFA concentrations of BAL and EBC were compared with a Mann-Whitney U test.

Results

Twenty subjects were enrolled into the study. Of these, 13 subjects had sufficient volumes of both EBC and BAL available for SCFA and microbiome assays. The median (interquartile range [IQR]) age of our sample was 59 (48–64) years, 59% of subjects were female, and 85% were white. Four subjects were current smokers, two were former smokers, and seven had never smoked; the median (IQR) pack-years of smokers was 20 (11–21). The median FEV₁% predicted (IQR) was 91% (83–104%), and the FEV₁/FVC ratio (IQR) was 0.87 (0.82–0.95).

SCFAs are in the water. All water samples (negative control samples) had detectable SCFA concentrations as measured by GC-MS (Figure 1); this finding was corroborated by an LC-MS assay (https://doi.org/10.7302/wk4r-7x52). Acetate was profoundly
