Short running title: Victorian trabeculectomy audit
Received 31 August 2016; accepted 9 March 2017
Conflict of interest: None
Funding sources: None
**ABSTRACT**

**Importance:** This study highlights the efficacy and safety of trabeculectomy in Victoria, Australia.

**Background:** Trabeculectomy is currently the gold-standard in glaucoma surgery. However, its role has been increasingly questioned due to its associated risks and complications. This audit aimed to assess the efficacy and safety of trabeculectomy surgery in the state of Victoria, Australia.

**Design:** A cross-sectional, retrospective, and voluntary state-wide audit of trabeculectomy surgery by individual surgeons in 2012 with 24-months follow-up.

**Participants:** Twenty-four surgeons in the state of Victoria submitted data on 227 trabeculectomies.

**Methods:** Basic pre- and peri-operative data were collected. Post-operative data collected included intra-ocular pressure (IOP) measurements, glaucoma medications, associated complications and subsequent surgery up to 24-months post-trabeculectomy.

**Main Outcome Measures:** Post-operative IOP and surgical complications.

**Results:** At 12-months, the mean IOP was 12.6 ± 4.1 mmHg (range 3-28 mmHg). A total of 91% of eyes had an IOP ≤18 mmHg with or without ocular hypotensive medications. One-third of eyes that were phakic at the time of trabeculectomy underwent cataract extraction within the 24-months of follow-up. Eyes that underwent combined cataract extraction and trabeculectomy (23% of trabeculectomies) had a significantly higher mean 12-month IOP than eyes that...
underwent trabeculectomy alone (13.9 mmHg versus 12.2 mmHg, p=0.01). At 24-months, there were no cases of blebitis/endophthalmitis.

**Conclusions and Relevance:** The Victorian Trabeculectomy Audit demonstrates excellent efficacy and safety results that are comparable to international standards. Combined cataract extraction and trabeculectomy tended to result in a higher mean post-operative IOP than trabeculectomy alone.

**Key words:** Glaucoma, trabeculectomy, filtration surgery, wound healing, antimitabolite, anti-fibrotic

**INTRODUCTION**

Trabeculectomy was introduced by Cairns in 1968 and remains the most commonly performed procedure for the treatment of medically uncontrolled glaucoma. Although technical aspects of the procedure have evolved over time, the underlying concept of the operation has changed little since Cairns’ original description. It is still regarded as the gold-standard glaucoma operation.

Reduction of subconjunctival scarring and improvement in long-term safety have been the main motivations behind the evolution in trabeculectomy. Wound-healing modulation through the use of antimetabolites such as 5-fluorouracil (5-FU) and Mitomycin C (MMC) has seen an increase in long-term bleb survival due to a reduction in subconjunctival scarring. However, the introduction of antimetabolites has also been associated with significant sight-threatening complications, such as hypotony, late bleb leak, and endophthalmitis. Alterations in the surgical technique have been developed – such as addressing antimetabolite concentration, treatment area and application time, irrigation of the surgical site after antimetabolite application, conjunctival management and closure, and aqueous...
flow regulation with the placement of adjustable and releasable trans-scleral sutures\textsuperscript{14} - to diminish the rates of these sight-threatening complications.

Published data of improved outcomes as a result of these technique modifications have largely come from single surgeons and/or centres.\textsuperscript{2,5,15,16} There has only been one associated study from Australasia on the subject, in the form of a postal questionnaire focused primarily on the use of antimetabolites in trabeculectomies.\textsuperscript{17} Recently Kirwan \textit{et al.}\textsuperscript{18} published a cross-sectional survey of trabeculectomy outcomes from nine glaucoma units in the United Kingdom (UK), which demonstrated that 87\% of 428 eyes achieved IOP of ≤21 mmHg at 2 years with or without ocular hypotensive medications. The bleb-related endophthalmitis rate was 0.5\% and no patient lost perception of light. This study has established the new benchmark for trabeculectomy outcomes in the UK.

To achieve a better understanding of both the nature of trabeculectomies performed in our own region and also their outcomes in comparison to other published data – particularly the study by Kirwan \textit{et al.}\textsuperscript{18} – we conducted a cross-sectional, state-wide audit of the current performance of primary trabeculectomies in Victoria, Australia.

**METHODS**

All Victorian ophthalmologists who were registered fellows of the Royal Australian and New Zealand College of Ophthalmologists (RANZCO) were invited by email to conduct a personal audit of primary trabeculectomies performed in their private practice for a calendar year. Primary trabeculectomy was defined as the first intraoperative glaucoma operation performed on the eye (excluding isolated lens surgery for a glaucoma indication). Previous selective laser trabecuoplasty or other outpatient laser procedures were permitted, but eyes with prior cyclodiode laser
therapy were excluded. The year 2012 was selected to allow for a 2-year follow-up period. An Excel spreadsheet (Microsoft Corp, Redmont, WA) with labeled columns of the required information was attached to the email. Each patient was coded within the spreadsheets for confidentiality.

Pre- and peri-operative data requested included: number of trabeculectomies performed by the surgeon over the 12-months, patient risk factors for failure (including age <30 years, history of uveitis, secondary glaucoma or cicatrizing disease, and previous conjunctival surgery), adjunctive antimetabolite usage and type, and whether concurrent cataract extraction was performed.

Post-operative data requested included: IOP at 12-months, number of eyes with IOP <18 mmHg with or without ocular hypotensive medications, number of post-operative antimetabolite injections, number of subsequent bleb needlings with or without antimetabolite, incidence of early or late blebitis, incidence of severe visual loss following trabeculectomy, and whether subsequent cataract surgery was performed. Severe visual loss was defined as a reduction in visual acuity to light perception (PL) or no light perception (NPL).

Participating ophthalmologists returned the completed spreadsheets and the data were collated and analysed with the assistance of a bio-statistician. These per-surgeon summaries were pooled using meta-analytic methods. Pooled estimates were calculated separately for two study groups: surgeons with more than 10 surgeries and those surgeons with 10 or fewer surgeries. For intraoperative use of MMC, the Stata command ‘metaprop’ used the Freeman-Tukey Double Arcsine Transformation\textsuperscript{19} to stabilize the variances for the per-surgeon proportions, and the random effects method to calculate pooled estimates of proportion and 95% confidence intervals based on score (Wilson).\textsuperscript{20} For 12-month IOP, the command
‘metan’ used the per-surgeon mean and standard error, and the DerSimonian & Laird random effects method to calculate pooled estimates of mean and 95% confidence interval. Estimates of heterogeneity were taken from the inverse-variance fixed-effect model. Forest plots were produced sorted by number of surgeries performed and stratified by study groups.

All tests were two-tailed and p-values are quoted where appropriate. Ethics approval was obtained from the Royal Victorian Eye and Ear Hospital (RVEEH) Human Research and Ethics Committee.

RESULTS

Three hundred and eighty-nine primary trabeculectomies were performed in 2012 in Victoria according to Medicare’s database (Medicare Benefit Schedule (MBS) code 42746), which annotates private practice activity. Twenty-four surgeons participated in the audit and submitted data on all the trabeculectomies they performed privately in 2012. Collectively they performed 227 trabeculectomies, accounting for 58% of the total number of Victorian private practice trabeculectomies in 2012. The number of trabeculectomies performed per surgeon ranged from 1 to 56, with 5 of the 24 surgeons (21%) being responsible for 141 cases (62.1%), and 16 surgeons (67%) performing fewer than 10 trabeculectomies that year (see table 1).

Two hundred and twenty of the 227 cases (97%) underwent trabeculectomy with adjunctive antimetabolite, with MMC accounting for 185 cases (81.5%) and 5-FU the remainder. No other anti-scarring agent was used in any of the cases. All forty-eight eyes (21.1%) that had one or more risk factors for failure underwent trabeculectomy with an antimetabolite; 47 with MMC, and one with 5-FU.
Post-operatively, 91 eyes (41.4%) received 5-FU injections without bleb needling; the range of 5-FU injections was 1-9 injections per eye across the 24-month follow-up period. Thirty-two cases (14.1%) underwent bleb needling post-operatively, 4 of which were performed without an adjunctive antimetabolite, with a range of 1-6 needlings/eye (total number of needlings = 59). Antimetabolite use, both intra- and post-operatively has been displayed in figure 1.

Fifty of the 227 trabeculectomies (22%) in this audit were performed in conjunction with phacoemulsification cataract surgery. Ninety-four (41%) eyes were pseudophakic at the time of trabeculectomy, and a further 28 (12%) went on to undergo cataract extraction during the 24-month follow-up period; this represented 34% of the patients who were phakic following trabeculectomy.

At 12-months, the mean IOP was 12.6 ± 4.1 mmHg (range 3-28 mmHg): 178 cases (78.4%) had an IOP of ≤18 mmHg without any ocular hypotensive medications (complete success); a further 29 (13%) eyes achieving IOP ≤18 mmHg with ocular hypotensive medication (qualified success). A total of 218 eyes achieved <21 mmHg with or without ocular hypotensive medications (96%). There was no statistically significant difference in 12-month IOP when comparing whether the surgeon performed <10 or ≥10 trabeculectomies that year, whether antimetabolites were used, or the type of antimetabolite used. However, eyes that underwent combined cataract extraction and trabeculectomy had a significantly higher mean 12-month IOP than eyes that underwent trabeculectomy alone (13.9 mmHg versus 12.2 mmHg, p=0.01) (figure 2). Table 2 outlines the management and outcome differences between eyes that underwent trabeculectomy alone versus combined cataract extraction and trabeculectomy.
At 24-months, there were no cases of early or late blebitis/endophthalmitis. However, 3 of the 227 cases (1.3%) sustained severe visual loss following filtration surgery.

**DISCUSSION**

Glaucoma surgery is currently undergoing a considerable 'facelift' with the introduction of minimally invasive glaucoma surgery (MIGS). The advent of MIGS is due in part to the potentially devastating complications associated with conventional glaucoma operations. Whilst it is widely recognised that MIGS is unlikely to achieve the level of IOP reduction that a trabeculectomy can achieve - but may rather decrease topical medication dependency - it does invite a reappraisal of the role of glaucoma filtration surgery in the 21st century.

This study demonstrates that trabeculectomy is still a successful operation in the treatment of glaucoma, based on IOP outcomes. Approximately 80% of cases achieve ≤18 mmHg without ocular hypotensive medications at 12-months, and 90% achieve this if ocular hypotensive medications are added; a total of 218 eyes achieved <21 mmHg with or without ocular hypotensive medications (96%). This is comparable to a UK study by Kirwan et al, which demonstrated that 78% achieved complete success and 86% achieved qualified success at 2 years. There were also no cases of blebitis or endophthalmitis reported in the 2-year follow up period in this cohort, which is therefore comparable to the rate reported by Kirwan et al (0.23%).

Compared to a report on previous practices in Australia (Liu et al.) and other studies, Victorian surgeons are now more likely to use MMC as an adjunctive antimetabolite than other agents, with MMC utilized in 85% of cases, compared to 63% in the
study by Kirwan et al.,\textsuperscript{18} and only 12\% in the study by Liu et al. which dates from 2008 and presumably reflects practice shortly prior to that.\textsuperscript{17} This study also demonstrated a higher frequency of postoperative antimetabolite injections without needling compared to the British study (41\% vs. 28\%).\textsuperscript{18}

Twenty-three percent of the trabeculectomies performed in this study were combined with cataract surgery. Combined cases were excluded from the UK study by Kirwan et al. and therefore the frequency with which they are performed is not known. However, combined surgery is the one factor that affected the 12-month IOP in our analysis. Indeed, if the combined cases were removed from the analysis, even better results were demonstrated with 99\% achieving \textless 18 mmHg with or without ocular hypotensive medication. A significantly higher proportion of cases were pseudophakic by the time they required trabeculectomy in our cohort compared to the cohort of Kirwan et al (43\% vs. 13\%). A further 13\% of eyes in our cohort went on to require cataract surgery in the 2-year follow-up period; this represents 34\% of eyes that remained phakic following glaucoma filtration surgery. Interestingly, Kirwan et al. reported a very similar number of eyes requiring cataract surgery in the 24-months subsequent to trabeculectomy (31\%).

The ideal timing of cataract surgery in relation to glaucoma surgery is debated. It is recognised that cataract surgery negatively affects the function of an existing bleb, especially with less time elapsed between trabeculectomy and cataract surgery.\textsuperscript{22} On the other hand, trabeculectomy within 6 months of cataract surgery may be associated with a higher rate of failure.\textsuperscript{23} Finally, combined surgery has been reported to have a lower success rate and higher rate of bleb failure compared to trabeculectomy alone,\textsuperscript{24,25} and this is consistent with our findings. We can only speculate whether the comparatively higher rate of pseudophakic patients at the time of trabeculectomy in Victoria – as compared to the UK – represents efforts by
local surgeons to 'clear the ground' in preparation for trabeculectomy, or may instead reflect the Australian private practice population versus the UK NHS population, particularly in relation to rates of lens extraction.

The role of the general ophthalmologist in the performance of trabeculectomy is an ongoing discussion: the number of trabeculectomies performed has decreased with the development of more effective medications and laser therapy.\textsuperscript{26} Compared to the study by Liu \textit{et al.}\textsuperscript{17} reporting that 75\% of respondents across Australia and New Zealand performed less than 10 trabeculectomies/year, the number of surgeons performing less than 10 trabeculectomies in a year has reduced to 67\% in our study. Certainly in the study by Kirwan \textit{et al.},\textsuperscript{18} only glaucoma units led by fellowship-trained glaucoma specialists were surveyed for the purpose of establishing a benchmark. Many would argue that less than 10 cases per year is suboptimal for maintaining surgical excellence for a sub-specialised procedure. We compared the outcomes of cases performed by surgeons who conducted <10 trabeculectomies with those who conducted \geq10 trabeculectomies in 2012, however, and identified no significant differences in 12-month IOP or complication rates, which is an encouraging result when bench-marked against the sub-specialist-led UK study results. The updated curriculum guidelines of RANZCO retain trabeculectomy as a core learning skill for an ophthalmology trainee.\textsuperscript{27}

This study has several limitations, foremost of which is the obvious responder selection bias. As a voluntary, surgeon-conducted audit, it is conceivable that more surgeons may have conducted the audit on their own patient cohort but then declined to submit their data due to undesirable outcomes discovered, even given that data were de-identified. Therefore our results may not reflect accurately the true Victorian trabeculectomy outcomes. Secondly, many other factors could have influenced the trabeculectomy outcomes, such as type of glaucoma, indication for
surgery, pre-operative IOP, length of pre-operative glaucoma medication usage, and specific surgical technique. However, to maximise the ease of data collection and submission, we elected to request core information only. Finally, we are guarded in our comparison of outcomes to the UK study – and others that were conducted on public hospital patients – as our cohort was managed entirely in the private sector, therefore excluding the involvement of trainee surgeons and other potential differences such as restrictions in follow-up appointments in public sector clinics. An audit of the outcomes of the trabeculectomies performed in the Victorian public hospital system would be of much interest for future study as a direct comparison to this study and also to the study by Kirwan et al.

The Victorian trabeculectomy audit has demonstrated excellent IOP and safety outcomes that are comparable to the best-reported international standards. It has identified a trend to more MMC usage in the choice of adjunctive antimetabolite in trabeculectomy. Trabeculectomy combined with cataract surgery tends to result in a higher mean post-operative IOP than trabeculectomy alone. However, just over one-third of phakic patients required cataract extraction in the 24-months following trabeculectomy. Surgical volume does not appear to be correlated with IOP outcomes from trabeculectomy. Based on our findings, trabeculectomy remains a realistic surgical option for the treatment of glaucoma in Australia.
