Dear Editor

Winter et al.1 concluded that open appendicectomy (OA) appears to be a safer approach for pregnant patients with suspected appendicitis. The observational data set was unbalanced with a zero event rate in the OA group and the total event rate was too small for valid regression analysis. Propensity Score Matching (PSM) was used for causal inference. However recent evidence demonstrated that PSM generates higher levels of imbalance, model dependence and bias.2 Furthermore, Boosted Regression cannot overcome non-informative predictors or important predictors that have been overlooked.3

A straightforward test (exact, unconditional) of difference in 2 binomial proportions showed a difference of 5.6% foetal risk between OA and LA (laparoscopic appendicectomy). As the data were acquired neither by random sampling nor by randomization, there is no population to which one could refer and thus no meaning could be attached to the 95% confidence interval stated.

The authors claimed that the results showed clinically relevant foetal risk but how was “clinically relevant” defined?

LA for pregnant mothers have consistently demonstrated benefits in terms of shorter operative times, length of stay and fewer postoperative complications compared to OA -- “the best way to take care of the baby is to take care of the mother”.4

As yet, there is no evidence-based pathophysiological explanation for the observed foetal risk with LA. Until then, there will be conflicting reports in the literature.5

To summarise, factors other than the surgical approach might have caused the observed difference and this study has not ruled out bias, confounding and chance and should not serve as an argument against the use of LA for suspected appendicitis in pregnancy. In observational studies causality can be established only on non-statistical grounds.
