SUMMARY
This paper develops a new active fault tolerant control system based on the concept of analytical redundancy. The novel design presented here consists of an observation filter based fault detection and identification system integrated with a nonlinear model predictive controller. A number of observation filters are designed, integrated with the nonlinear controller and tested before reaching the final design which comprises an unscented Kalman filter for fault detection and identification together with a nonlinear model predictive controller to form an active fault tolerant control system. 1. INTRODUCTION
Fault Detection and Identification (FDI) is a very mature field of study and provides many powerful quantitative and/or qualitative modelling tools. Most FDI research does not include a combined controller and FDI design [1], [2]. The ultimate goal of FDI is the provision of fault information to the controller to enable active fault tolerant control (FTC). However, the main difficulty with active fault tolerant control (FTC) is on-line reconfiguration, which requires detailed information about changes in system parameters. Hence the main role of the FDI subsystem has been the gathering of information on parameter changes to assist in controller reconfiguration. In this paper we present an active FTC system design based on a nonlinear model predictive control system integrated with an unscented Kalman filter for fault detection and parameter estimation. While there are many observer based FTC systems in the literature the novelty of our work is that this is the first time a unscented Kalman filter (UKF) has been integrated with a nonlinear model predictive controller for fault tolerant control.

By nature a fault causes a system to behave abnormally but does not cause the system to shut down [3]. On the other hand, when left unattended a fault may lead to a system failure emphasising the importance of an FTC system. Since faults can cause instability in a system, the integration of an FTC scheme significantly increases the ability of the system to maintain overall stability in the presence of a fault [2]. In this paper we develop a new active FTC system using an unscented Kalman filter (UKF) for fault detection and identification (FDI) where parameter updates made by the UKF are sent to the nonlinear model predictive control (MPC) based control system. Based on the estimates provided by the UKF the nonlinear model predictive controller updates its internal.
process model to obtain optimal control inputs given the most current up to date system information. To test the FTC system the design is applied to the control of a 2D robot model.

Numerous solutions exist for the FTC design problem with the FTC research community classifying these designs as either active or passive. Passive FTC systems, based on fixed controllers, are designed to be resilient against known faults and use robust control techniques for worst case scenarios. Active FTC systems, on the other hand, “actively” seek the fault and try to gather as much information about it as possible to help the controller overcome any consequential instabilities and are also known as self-repairing, self-designing or fault detection, identification (diagnosis) and accommodation schemes. Active schemes are made up of an FDI component and are based on controller redesign, or selection/mixing of pre-designed controllers.

Most reconfigurable controllers use real time estimates of the system parameters provided by parameter estimation based FDI. These approaches to FDI are thought to provide the controller with system information in a more suitable format for on-line reconfiguration than the alternative approaches based on state estimation. Many difficulties still exist in parameter based estimation techniques. For example, in order to get good estimates it may be necessary to introduce perturbation signals to ensure all plant modes have been sufficiently excited; this is particularly true for aircraft [1]. Hence while the combination of an observer and controller for FTC is quite common [4], [5], [6] this is the first time that nonlinear model predictive control using pseudospectral discretisation numerical techniques is combined with an unscented Kalman filter to form an active FTC system. Moreover we design and compare an extended Kalman filter and two forms of the integrated multiple model filter based FTC systems with the UKF based system coming to the conclusion that the UKF filter is the best one for this purpose.

Observer based FDI schemes are very dependent on the models upon which the scheme is designed. Hence the reliability of these FDI systems must be higher than the monitored system. The better the model representing the dynamic behaviour of the system the higher the possibility of improving the reliability and performance in detecting and isolating faults. Plant model mismatches can cause false alarms, or even miss faults, and hence robustness issues in FDI are very important [7]. One of the advantages of MPC is the easy incorporation of robust control ideas [8].

Techniques commonly used for FDI include artificial intelligence based FDI schemes [9], [10], [11], and multiple model based methods [12] [3]. In the latter case different models are used to describe the dynamics of the system for different operating regimes. Sliding mode observers for fault detection have also been used because of their strong robustness to a particular class of uncertainty [13]. Other methods include analytical FDI methods that are based on estimating the fault through matrix algebra [14]. Observer based FDI remains the most common approach studied in recent literature where an extended state observer is used to estimate faults.

With regards to FTC, hardware redundancy and full self diagnosis equipment have been used in some cases but are not always viable solutions due to excessive costs and an increase in system weight. Consequently other means of FDI are necessary, such as using the available data and the mathematical model of the plant; this is referred to as model-based FDI, and as analytical redundancy (AR). This approach to FDI is based on the belief that when a fault occurs the physical parameters change and as a result the dynamical model of the plant also changes. The residual generation approach, using observers such as the Kalman filter [15], the Unscented Kalman Filter [16] and Multiple Model Filters [17], is the most researched area in FDI [7] and is investigated as part of this research. While these filters have been researched for fault detection this is the first time that they are being integrated with a pseudospectral based nonlinear model predictive control controller within the context of fault tolerant control for application to systems outside of the process industry.

Quite often in the design of an FTC system two controllers are utilised; the main (or nominal) controller is designed for the faultless case with the second controller being a compensator designed to handle the faulty case [18]. In this paper a number of observer based FDI schemes are investigated and integrated with the NMPC to develop a full active FTC system. In our design only one controller needs to be designed capable of handling the faultless as well as the fault cases.
This paper is organised as follows; section 2 presents the essential background on the FDI methods chosen for investigation, namely the EKF (extended Kalman filter), the UKF (unscented Kalman filter) and the IMM (integrated multiple models). An EKF filter, UKF filter, EKF based IMM filter and a UKF based IMM filter are each designed in section 3 for the purposes of FDI using a 2D robot model. Four different active fault tolerant control systems using NMPC as the controller design are formulated and implemented in MATLAB for the 2D robot model. Each of the four different active FTC systems developed are then tested under different conditions in section 4. These tests were designed to evaluate the performance of the filters as well as the interaction of the filter and controller designs. Section 4 provides a detailed analysis of the test results and concludes with a summary of findings. Based on the findings the UKF filter was chosen as part of the final design of the active FTC system. Section 4 concludes with a comparison between linear MPC and nonlinear MPC as the controller showing that an active FTC system with a nonlinear MPC controller has better overall performance in the event of a failure. A discussion section has been provided in section 4.7 followed by the conclusions given in section 5.

## 2. FAULT DETECTION TECHNIQUES SELECTED FOR IMPLEMENTATION: THEORETICAL DESCRIPTION

The fault detection schemes considered here are all based on filtering techniques, namely the EKF, the UKF, the EKF based IMM and the UKF based IMM. These filters are used to sequentially estimate the state of a dynamic system using a sequence of noisy measurements made on the system. The state estimates are then utilised to aid in fault detection and control reconfiguration. A brief overview and key mathematical concepts are provided for each method below.

### 2.1. Extended Kalman Filter (EKF)

The EKF is an extension of the well known Kalman filter. A drawback of the Kalman filter is that it does not provide good estimations for nonlinear systems [19]. The EKF approximates (or linearises) the nonlinear functions in the state dynamic and measurement models. There are two main stages during an EKF (and the general Kalman filter) cycle: predict and update. During the prediction stage the filter states and covariances are predicted forward one time step as are the measurement predictions. During the update stage corrections are made to the state predictions via noisy measurements. A summary of the EKF (Ristic et al [19]) equations is given below. The target state \( x_k \) and measurement \( z_k \) equations propagate according to:

\[
\begin{align*}
\dot{x}_k &= f_k(x_{k-1}) + v_{k-1}, \\
\dot{z}_k &= h_k(x_k) + w_k,
\end{align*}
\]

where \( v_{k-1} \) and \( w_k \) are random sequences and are mutually independent with zero-mean, white Gaussian with covariances \( Q_{k-1} \) and \( R_k \) respectively. The EKF is based on the assumption that local linearisation of the above equations may be a sufficient description of nonlinearity. The mean and covariance of the underlying Gaussian density are computed recursively in a two stage process (Ristic et. al [19]):

**Stage 1: Prediction**

\[
\begin{align*}
\dot{x}_{k|k-1} &= f(\dot{x}_{k-1|k-1}), \\
P_{k|k-1} &= Q_{k-1} + F_{k-1}P_{k-1|k-1}F_{k-1}^\top.
\end{align*}
\]

**Stage 2: Update/Correction**

\[
\begin{align*}
\dot{\hat{x}}_{k|k} &= \dot{x}_{k|k-1} + K_k\nu_k, \\
P_{k|k} &= P_{k|k-1} - K_kS_kK_k^\top,
\end{align*}
\]

where \( \nu_k = z_k - h_k(\dot{x}_{k|k-1}) \), \( S_k = \hat{H}_kP_{k|k-1}\hat{H}_k^\top + R_k \) and \( K_k = P_{k|k-1}\hat{H}_k^\topS_kK_k^\top \). The parameter \( K_k \) is commonly known as the Kalman gain and \( S_k \) is referred to as the innovation.
The innovation \( \nu_k \) is the error between the predicted measurement and the actual measurement of the system. The matrices \( \hat{F}_{k-1} \) and \( \hat{H}_k \) are the local linearisation of the nonlinear functions \( f_{k-1} \) and \( h_k \). The two matrices are defined as Jacobians evaluated at \( \hat{x}_{k-1|k-1} \) and \( \hat{x}_{k|k-1} \) respectively (Ristic et. al [19]). The non-Gaussianity of the true posterior density is more evident, for example becomes bimodal or heavily skewed, when the model is highly nonlinear. In this event the performance of the EKF will significantly degrade.

2.2. The Unscented Kalman Filter (UKF)

The UKF addresses the issue of non-Gaussianity. The UKF is a part of a family of nonlinear filters, referred to as linear regression Kalman Filters, that are based on statistical linearisation rather than analytical linearisation. The key concept behind these filters is nonlinear filtering using a Gaussian representation of the posterior \( p(x_k|Z_k) \) through a set of deterministically chosen sample points. The true mean and covariance of the Gaussian density are completely captured by these sample points up to the second order of nonlinearity, with errors introduced in the third and higher order when propagated through a nonlinear transform. The EKF on the other hand is only of first order with errors introduced in the second and higher orders. The filters belonging to this family differ only by the method used to select the sample points i.e. their number, weights and values in the filtering equations are identical and are given below. The UKF uses an unscented transform for the selection of points in an EKF framework (Ristic et. al [19]).

We assume that at time \( k-1 \) the posterior is Gaussian: \( p(x_{k-1}|Z_{k-1}) \approx \mathcal{N}(x_{k-1}; \hat{x}_{k-1|k-1}, P_{k-1|k-1}) \). The very first step is representing this density via a set of \( N \) sample points \( \lambda^i_{k-1} \) and their weights \( W^i_{k-1}, i = 0, \ldots, N - 1 \). The UKF uses the unscented transform [19] to select the sample points \( \lambda^i_{k-1} \) and weights \( W^i_{k-1} \). The prediction step is as follows:

\[
\hat{x}_{k|k-1} = \sum_{i=0}^{N-1} W^i_{k-1} f_{k-1}(\lambda^i_{k-1}),
\]

\[
P_{k|k-1} = Q_{k-1} + \sum_{i=0}^{N-1} W^i_{k-1} [f_{k-1}(\lambda^i_{k-1}) - \hat{x}_{k|k-1}] [f_{k-1}(\lambda^i_{k-1}) - \hat{x}_{k|k-1}]^\top.
\]

A set of \( N \) sample points:

\[
\lambda^i_{k|k-1} = f_{k-1}(\lambda^i_{k-1}),
\]

are used to represent the predicted density: \( p(x_k|Z_{k-1}) \approx \mathcal{N}(x_k; \hat{x}_{k|k-1}, P_{k|k-1}) \) and the predicted measurement becomes:

\[
\hat{z}_{k|k-1} = \sum_{i=0}^{N-1} W^i_{k-1} h(\lambda^i_{k-1}).
\]

The update step is defined as:

\[
\hat{x}_{k|k-1} = \hat{x}_{k|k-1} + K_k \nu_k,
\]

\[
P_{k|k} = P_{k|k-1} - K_k S_k K_k^\top,
\]
where:

\[ K_k = P_{xz} S_k^{-1}, \]  

\[ S_k = R_k + P_{zz}, \]  

\[ P_{xz} = \sum_{i=0}^{N-1} W_{k-1}^i \left( \chi_{k|k-1}^i - \hat{x}_{k|k-1} \right) \left( h_k(\chi_{k|k-1}^i) - \hat{z}_{k|k-1} \right)^T, \]  

\[ P_{zz} = \sum_{i=0}^{N-1} W_{k-1}^i \left( h_k(\chi_{k|k-1}^i) - \hat{z}_{k|k-1} \right) \left( h_k(\chi_{k|k-1}^i) - \hat{z}_{k|k-1} \right)^T. \]  

As can be seen from the above filter equations there is no explicit calculation of Jacobians. Consequently these filters can be utilised even when the nonlinear functions \( f \) and \( h \) have discontinuities.

2.3. Interacting Multiple Model (IMM)

The IMM belongs to a class of filters called the Gaussian Sum Filters. The main concept here is the approximation of the required posterior density \( p(x_k|z_k) \) by a Gaussian mixture (Ristic et. al [19]):

\[ p(x_k|z_k) \approx p_A(x_k|z_k) = \sum_{i=1}^{q_k} w_k^i N(\chi_{k|k}^i; \hat{x}_{k|k}^i, P_{k|k}^i), \]  

where \( w_k^i \) are weights that are normalised, \( \sum_{i=1}^{q_k} w_k^i = 1 \). Gaussian sum filters such as the IMM are ideal when the posterior density is multimodal because multimodal densities lead to performance degradation in both the EKF and UKF. At time \( k \) the state estimate is calculated for each possible current model using \( r \) filters, with each filter using a different combination of the previous model-conditioned estimates called mixed initial condition. Details of the algorithm are highly documented and can be found in [21].

Now that we have outlined the details of the the methods chosen for further investigation, the EKF, the UKF and the IMM filters, we apply these to the 2D robot model in the next section.

3. PROBLEM FORMULATION

To test the different filtering techniques in an FDI context a robot model is used for development and testing purposes and forms the plant that is to be controlled as well as the process model of the NMPC controller (see figure 1).

The equations for this robot model are:

\[ \dot{x} = V \cos \psi, \]  

\[ \dot{y} = V \sin \psi, \]  

\[ \dot{\psi} = \frac{R(\omega_R - \omega_L)}{2b}, \]  

where \( x \) is the \( x \)-coordinate of the point \( C \), \( y \) is the \( y \)-coordinate of the point \( C \), \( \psi \) is the heading angle, \( \omega_R \) is the right wheel angular velocity, \( \omega_L \) is the left wheel angular velocity and \( V \) is the speed given by \( V = \frac{R(\omega_R + \omega_L)}{2} \).

The NMPC controller solves the following optimal control problem using pseudospectral discretisation:

\[ \min \left( \frac{t_f - t_0}{2} \right) \sum_{j=0}^{N} \left( \|\chi - x_{ref}\|^2_{Q_x} + \|V - V_{ref}\|^2_{Q_v} + \|\dot{\psi} - \dot{\psi}_{ref}\|^2_{Q_c} \right) w_j. \]  

This article is protected by copyright. All rights reserved.
subject to

\[
\frac{t_f - t_0}{2} D_{j,k} \dot{x}_j - \dot{x}_j = 0,
\]

\[
x(j_0) - x_{\text{dem}}(j_0) = 0,
\]

\[
x_{lb} \leq x \leq x_{ub},
\]

\[
u_{lb} \leq u \leq u_{ub},
\]

\[
\Delta \delta_{eb} \leq \Delta \delta_e \leq \Delta \delta_{eb}.
\]

Fifty coincidence points \((N = 50)\) are used along with a prediction window length of 5 secs \((H_p = 5)\). The weights \(Q_x, Q_V,\) and \(Q_\psi\) are diagonal matrices with the diagonal values (found through trial and error) set to 10, 1 and 1 respectively.

The fault, to be simulated and tested for, is a punctured wheel. If a wheel is punctured the radius of the wheel will decrease and so the filters are set up to estimate the radius of the wheel. Four different filters have been designed, the EKF, the UKF, the EKF IMM and the UKF IMM.

The robot parameters used for all simulations are: right wheel radius, \(R_R = 2\ m\), left wheel radius, \(R_L = 2\ m\), distance between wheels, \(b = 1\ m\), speed demand is \(10\ m/s\) and the input constraints on \(\omega_R\) and \(\omega_L\) are \(\pm 1000\ \text{deg/sec}\). The filters are updated at 100Hz while the controller is updated at 10Hz. All work was developed using MATLAB with SNOPT as the nonlinear programme (NLP) solver. The following subsections detail the design of each of the filters.

3.1. EKF Fault Detection Filter

The state vector for the EKF consists of the following states:

\[
x = [x, y, \psi, R_R, R_L]^T,
\]

where \(x, y\) and \(\psi\) are the robot states and \(R_R\) and \(R_L\) are the right wheel and left wheel radii respectively. The measurements are assumed to be of the speed, \(V\), of the robot:

\[
z = V(k) + w(k),
\]
where $w(k)$ is additive white noise. The initial state vector and initial covariance matrix are:

$$
\mathbf{x}(0) = \begin{bmatrix} x_0, \ y_0, \ \psi_0, \ 2, \ 2 \end{bmatrix}^T, \quad P(0) = \begin{bmatrix}
(0.5)^2 & 0 & 0 & 0 & 0 \\
0 & (0.5)^2 & 0 & 0 & 0 \\
0 & 0 & (1\pi/180)^2 & 0 & 0 \\
0 & 0 & 0 & (0.5)^2 & 0 \\
0 & 0 & 0 & 0 & (0.5)^2
\end{bmatrix}.
$$

(29)

The $Q$ and $R$ noise matrices were chosen to be:

$$
Q = \begin{bmatrix}
(5 \Delta t)^2 & 0 & 0 & 0 & 0 \\
0 & (5 \Delta t)^2; & 0 & 0 & 0 \\
0 & 0 & (0.1 \Delta t)^2 & 0 & 0 \\
0 & 0 & 0 & (2 \Delta t)^2 & 0 \\
0 & 0 & 0 & 0 & (2 \Delta t)^2
\end{bmatrix}, \quad R = (0.5)^2,
$$

(30)

where $\Delta t$ is the update rate of the filter. For the prediction cycle an Euler integration scheme is used to predict the states of the EKF forward to the next time step. The predicted measurement $\hat{z}$ is given by:

$$
\hat{z}(k) = V(k|k - 1).
$$

(31)

Given the above information the Kalman filter equations given in section 2.1 are applied to estimate the radius of each wheel in the experiments conducted in section 4.

### 3.2. UKF Fault Detection Filter

The general structure of the EKF and UKF are very similar in that they both have a prediction and update cycle and produce a single state vector and a corresponding covariance matrix. For the robot model the state vector is the same as the one given in equation (27). The initial state vector, initial covariance matrix, the process noise matrix $Q$ and the noise covariance matrix $R$ all remain the same as those given in subsection 3.1. The UKF algorithm given in subsection 2.2 is applied to the robot model with $\kappa = 0.001$ [20].

### 3.3. Interacting Multiple Model Fault Detection Filter

The interacting multiple model method, as the name suggests, is made up of multiple models where each model tests a different hypothesis. Four different models (the terms mode and model are used interchangeably and have the same meaning in the context of IMMs) have been designed where:

Model 1: No Fault case.

Model 2: 50% right wheel deflation, left wheel no fault.

Model 3: Right wheel no fault, 50% left wheel deflation.

Model 4: 50% right wheel deflation, 50% left wheel deflation.

During Step 3 of the IMM algorithm given in section 2.3 a filter such as the EKF is used to update the states and covariances, and both an EKF based IMM filter and a UKF based IMM filter have been designed. The initial covariance matrix for each filter and each mode are the same as equation (29). The $Q$ and $R$ matrices are those given in equation (30) and the initial state vectors for each filter and mode are:

$$
\mathbf{x}_1(0) = \begin{bmatrix} x_0, \ y_0, \ \psi_0, \ 2, \ 2 \end{bmatrix}^T,
$$

(32)

$$
\mathbf{x}_2(0) = \begin{bmatrix} x_0, \ y_0, \ \psi_0, \ 1, \ 2 \end{bmatrix}^T,
$$

(33)

$$
\mathbf{x}_3(0) = \begin{bmatrix} x_0, \ y_0, \ \psi_0, \ 2, \ 1 \end{bmatrix}^T,
$$

(34)

$$
\mathbf{x}_4(0) = \begin{bmatrix} x_0, \ y_0, \ \psi_0, \ 1, \ 1 \end{bmatrix}^T.
$$

(35)
The mixing probabilities or mode probabilities are initially set to:

\[ \mu = [1/4, 1/4, 1/4, 1/4]^T, \]  \hspace{1cm} (36)

and the mode transition probabilities matrix \( p \) is set to:

\[
p = \begin{bmatrix}
0.97 & 0.01 & 0.01 & 0.01 \\
0.01 & 0.97 & 0.01 & 0.01 \\
0.01 & 0.01 & 0.97 & 0.01 \\
0.01 & 0.01 & 0.01 & 0.97
\end{bmatrix}.
\]  \hspace{1cm} (37)

4. NUMERICAL RESULTS AND ANALYSIS

The robot is required to follow a circular path for all experiments. To simulate the measurement additive white noise is added to the speed of the robot which is calculated as a part of the truth simulations of the robot movement. To test the filters four different test cases were set up and each test case was run twice. During the first run the FDI feedback loop is not closed and the filters are used for estimation only. The FDI loop is closed during the second run to investigate the behaviour of the full active FTC controller. The test cases are as follows:

**Scenario 1:** No Fault. The objective is to investigate how well the filters estimate the radii of the tyres in a no fault situation.

**Scenario 2:** Left wheel 50% puncture. In this case a puncture is simulated to occur 10 secs into the simulation. The wheel is assumed to deflate to 50% of its original value instantaneously.

**Scenario 3:** Left and Right Wheel puncture. In this test case a left wheel puncture is simulated 5 secs into the run and a right wheel puncture is simulated to occur 10 secs into the simulation. Both punctures are assumed to cause an instantaneous reduction of the respective wheel radius to 50% of the original wheel radius.

**Scenario 4:** Left wheel linear puncture. In this test case once again the left wheel is punctured 10 secs into the run however this time the puncture is assumed to follow a linear reduction in wheel radius according to \( R_L = 2 - 0.1t \), where \( R_L \) represents the left wheel radius reduced from its original value of 2m down to 0.1m at a rate of 0.1m/s and \( t \) is the current time. The radius does not drop to 0m as this caused a complete system failure.

The results for each filter are presented in the next four subsections:

4.1. Scenario 1

Plots of the speed innovation were produced (but have been omitted due to space constraints) where the innovations were plotted along with the calculated 2\( \sigma \) uncertainty bounds. The 2\( \sigma \) uncertainty bounds are a 95% confidence interval and the solution (innovations in this case) must remain within the bounds 95% of the time. The results for the EKF and UKF filters showed that the speed innovations remained well within the uncertainty bounds throughout the duration of the run both with and without feedback. The speed innovation plots for the IMM filters were also produced. The results for both the UKF and EKF based IMM filters showed that the filters were able to very quickly detect the correct mode of operation.

Plots of the wheel radius estimates were also produced. All filters do a very good job of estimating the radius of the tyres with and without feedback. The IMM filters initially have a higher error in the tyre estimate as the estimation is based on a mixture of all the models, however it took only one update for the IMM to reach the correct estimate.
The wheel speed estimates (or angular rates) were also analysed and it was found that the estimates for all four filters were very similar. In the case of no feedback the estimate was the same as the actual speed; however in the case where feedback is provided the wheel speeds were quite noisy. This is a result of calculations based on noisy measurements which is a consequence of feedback.

Plots of the robot trajectory for all four filters showed that the robot remained on the path with and without feedback which is to be expected in the no fault case.

4.2. Scenario 2

The speed innovations for all four filters were plotted and the results showed that all filters were able to detect the fault. The fault occurred 10 secs into the run, and the plots show that at 10 seconds there was a peak change in the innovation curves. The corrections/innovations were seen to increase at the time the fault occurred and settle again near zero once the correct estimate was reached.

For the IMM filters model 3 is the correct match for scenario 2 and both of the IMM filters were seen to find the correct mode immediately as mode 3 is the most confident in its estimate. Mode 3 and Mode 4 both hypothesise a failure in the left wheel of 50% which is why after the occurrence of the fault the uncertainties do not increase. However because mode 1 and mode 2 do not hypothesise a fault in the left wheel the uncertainties can be seen to increase once the fault has occurred. The uncertainty in mode 3 was seen to decrease twice as much compared to mode 4 after the fault occurred. This is because mode 4 hypothesises that both wheels are punctured whereas mode 3 predicts the puncture of only the left wheel. Another point to note is that in the single filter cases feedback did not have much effect on the innovations. However, in the case of the IMM filters the results show that with feedback the filter errors do not grow as rapidly between updates. The errors are seen to grow very quickly when no feedback is present which is evident in figures 2 and 3.

The results for the wheel radius estimates showed that the UKF estimates were closer to the actual wheel radius compared to those produced by the EKF. Turning on feedback results in the filters reaching a steady estimate faster when compared to the no feedback case. The IMM filters produced slightly better estimates than the single UKF filter and there was very little improvement on the IMM estimates compared to the no feedback case.

The wheel speeds were also analysed and the results for all four filters presented the same trends. Without feedback there is much more activity present compared to turning on the feedback. Once the fault occurs the robot yaws to the side with the punctured wheel and demands a faster speed to compensate for the loss in radius.

The robot trajectories were simulated and all results showed that the robot was only able to remain on the path if feedback from the filter was provided to reconfigure the controller. Although all filter estimates without feedback were excellent, without reconfiguration of the controller the robot could not be made to follow the desired path (see figure 4 for results of the UKF).
4.3. Scenario 3

The plots of the speed innovations for all filters clearly indicated, from the sudden changes in innovations, the detection of both faults, left wheel at 5 secs and right wheel at 10 secs. The EKF innovations were found to be consistent, however the innovations produced by the UKF show that, with feedback, the innovation uncertainty begins to grow rapidly between updates whereas without feedback the uncertainty remains constant (see figure 5 for UKF results). The IMM filters show that after 5 secs model 3 is the best model. However, once the second fault occurs the filters do an excellent job of recognising that mode 4 is the correct match and uncertainties in mode 4 are seen to decrease (see figure 6 for IMM EKF plots). It was again observed in the no feedback case that the uncertainties on the IMM filters grow rapidly between updates and many more corrections are required.

The wheel radius estimates produced by the filters showed that the IMM filters produce the best estimates of the radii. The UKF performs slightly better than the EKF, and turning feedback on results in a faster settling time (see figure 7 for UKF results).

Plots of the angular rates achieved by the robot via the EKF showed that once a fault occurred the punctured wheel is required to spin faster in order to compensate for the loss in radius. The angular rates produced as a result of the UKF, with feedback, resulted in operation at the angular rate constraints. Both IMM filters displayed similar behaviour in that once a wheel was punctured it was required to rotate faster to compensate for the loss in radius.
The trajectories produced by each filter for scenario 3 showed that without feedback it is impossible to maintain the robot on the path. Reconfiguring the controller on the other hand with estimates from the filters allowed the robot to easily follow the reference path. An anomaly occurred with the UKF filter where even turning the feedback on did not result in the robot following the path.
after the occurrence of the second fault. This could possibly be the result of poor tuning of the filter (see figure 8 for results of the UKF).

![Figure 8. Scenario 3: UKF Trajectory](image)

4.4. Scenario 4

Scenario 4 speed innovations are presented in figures 9 and 10 for the EKF and UKF respectively. The EKF breaks down 5 seconds after the fault occurs, when feedback is turned on as can be seen by the innovations exceeding the covariance bounds. Without feedback however the innovations remain within the uncertainty bounds. The results from the UKF are much better as it produces innovations which remain well within the uncertainty bounds with and without feedback. Both of the IMM filters failed, because the fault type of scenario 4 was not modelled as a part of the filter design, i.e. the hypothesis for this type of failure is not accounted for and so no model exists for this failure (see figure 11 for UKF-IMM results).

![Figure 9. Scenario 4: EKF Speed Innovations, 2σ Uncertainty Bounds (red), Speed Innovations (blue)](image)

The wheel radius estimates showed that without a hypothesis on the IMM filters the UKF was the only filter able to produce the correct estimates of the wheel radii. The UKF results clearly indicated that reconfiguring the controller resulted in a faster convergence to the correct estimate.

Plots of wheel speed produced by all four filters with and without feedback show that with this type of fault both wheels were required to work at their constraints.
The robot trajectories as a result of the different filter information were examined and it was found that none of the filters show full compliance with the reference trajectory. However the UKF was able to maintain the robot on the path the longest.

4.4.1. Filter Re-Design - This subsection looks at the behaviour of the IMM filters by re-designing the filters to accommodate the fault type covered by scenario 4. The filters were modified by adding a fifth model, which hypothesises the left wheel puncturing in the manner described by scenario 4. The $Q$ and $R$ matrices remain the same and the initial state vectors for the fifth filter and mode are:

$$\mathbf{x}_5(0) = \begin{bmatrix} x_0, & y_0, & \psi_0, & 2, & 2 \end{bmatrix}^\top.$$  \hfill (38)

The mixing probabilities or mode probabilities become:

$$\mu = [1/5, 1/5, 1/5, 1/5, 1/5]^\top,$$  \hfill (39)

and the mode transition probabilities matrix $p$ is redefined as:

$$p = \begin{bmatrix} 0.96 & 0.01 & 0.01 & 0.01 & 0.01 \\ 0.01 & 0.96 & 0.01 & 0.01 & 0.01 \\ 0.01 & 0.01 & 0.96 & 0.01 & 0.01 \\ 0.01 & 0.01 & 0.01 & 0.96 & 0.01 \\ 0.01 & 0.01 & 0.01 & 0.01 & 0.96 \end{bmatrix}.$$  \hfill (40)

The speed innovations for the IMM EKF are presented in figures 12 and 13 with no feedback and with feedback respectively. As predicted the results show that if a hypothesis is made the IMM

Figure 11. Scenario 4: IMM UKF Speed Innovations With Feedback, $2\sigma$ Uncertainty Bounds (red), Speed Innovations (blue)
performs very well. The EKF as part of IMM is able to predict this type of error which it was unable
to do as a single filter. The IMM UKF speed innovation plots showed a higher level of confidence in
its estimates compared to its EKF counterpart as the uncertainty is lower and consistent. Providing
feedback in both cases (EKF and UKF IMMs) was shown to increase confidence in the filter
estimates.

Speed Innovations (blue)

Figure 13. Scenario 4: 5 Model IMM EKF Speed Innovations With Feedback, $2\sigma$ Uncertainty Bounds (red),
Speed Innovations (blue)

The UKF based IMM estimates of the wheel radii for the 5 mode IMM are shown in figure 14.
The results of both EKF and UKF based IMMs showed that in both cases the filters do an excellent
job of making the correct estimations on the radius of the wheel. The angular rate plots of the 5 mode
IMMs again showed that the control inputs are required to work at the constraints the majority of
the time once the fault occurred. This result is not dependent on the filter type but rather the fault
that has occurred makes it impossible for the robot to achieve the desired task while at the same
time respecting its constraints.

The trajectory plots showed that for this type of fault where the wheel radius had almost
approached zero, the wheels are unable to maintain the reference. The UKF IMM is again able
to keep the robot on the path for a longer time than the EKF IMM.

4.5. Filter Comparisons

The results of the previous section reveal that each of the filters considered exhibits excellent
qualities for fault detection and identification. Figure 15 shows a comparison of the different filters
in terms of wheel radius estimation. The plots in figure 15 show the radius estimates for scenario
which is the worst case scenario out of the 4 scenarios considered. The radii estimates from the EKF and the 4 mode IMM filters have been omitted as the errors were very large.

The plots in figure 15 show that in terms of wheel radius estimate performance, the UKF performance was equal to that of the 5 mode IMM filters. The IMM filters were able to reach the correct estimate faster than the single UKF. This is particularly evident when there is a sudden change, such as at the 10 second mark. The EKF performance also dramatically increases when used within an IMM configuration. The drawback of the IMM filter is that all possible scenarios must be accounted for.

Our research shows the easy adaptability of IMM to different situations, and the speed with which it is able to identify and reach the correct estimate. However predicting exactly how a fault will occur (in this case how a tyre will puncture) is impractical. A more practical implementation would be to develop a number of filters each with different process noises that could adapt to all different situations. The number of filters and the process noise values would then have to be determined by trial and error. In any case an IMM performs well if and only if it is equipped to make a hypothesis on the current situation. If the given situation is unaccounted for the filter breaks down. In terms of the single filter, in general the UKF displayed better performance than the EKF, especially in the case of scenario 4 where the non-linearities of the fault caused the single EKF to breakdown. For these reasons the UKF has been chosen for the final FTC system design.

4.6. Comparison to Linear MPC

In light of the results in subsection 4.5 only the UKF with feedback has been used in comparing linear and nonlinear MPC. The results given in the next two sections are for scenarios 2 and 4, respectively. Due to space constraints, only plots for scenario 2 are presented.
4.6.1. Scenario 2  The speed innovation plots in figure 16 produced by the linear MPC controller show that the innovations remain well within the uncertainty bounds and are approximately zero. However the uncertainty was seen to be double that produced by the nonlinear controller.

The wheel radii plots given in figure 17 show that the estimations produced by a nonlinear controller are the same as those produced by the linear controller. Hence the filter performs well even with linear MPC.

The angular rate plots for the linear MPC controller (figure 18) show that five seconds after the fault has occurred the linear controller pushes the wheels to operate at their constraints and is unable to tolerate the faulty condition. The angular rates produced by the NMPC controller (figure 19) show that it was able to easily adapt to the fault. This is further illustrated in the trajectory plot given in figure 20 which clearly shows that the nonlinear MPC controller does an excellent job of keeping the robot on the path despite a faulty wheel whereas the solution produced by the linear controller has diverged.

A point to note here is that while the trajectory tracking is good, the switching behaviour observed in wheel rotation rates is highly undesirable, and in the real world would produce wheel slippage, and high levels of wear on tyres and mechanicals. The wheel rates produced by the nonlinear MPC
controller show a dramatic decrease in this switching behaviour. It is, however, still present (figure 19). This limit cycle behaviour is a negative characteristic that needs to be addressed before this technique can be applied to real systems. This exercise was purely for proof of concept and further work would be needed in any practical application. The model is entirely kinematic and for it to
represent a more practical scenario further work is required to eliminate the limit cycling behaviour; for example by adding actuation activity to the cost function and an angular acceleration term to avoid wheel slippage issues.

4.6.2. Scenario 4

The speed innovations were plotted for scenario 4 and showed similar trends to those above in that the innovations are quite small; however the uncertainties with the linear controller are higher than those produced as a result of nonlinear MPC. The estimates of the wheel radii however are very good and were seen to be the same for both linear and nonlinear controllers.

As expected the linear controller was unable to maintain the robot on the path. Neither of the controllers were able to drive the robot to the path as the wheel radius had been reduced to almost zero, making it infeasible for the robot to continue. The angular rates showed that the linear controller constantly demanded operation at the constraints oscillating between the upper and lower limits continuously. The nonlinear MPC controller results for wheel angular rates showed that the right wheel oscillates between the upper and lower bounds, however the left wheel is required to constantly work at the upper bound.

4.7. Discussion

The simulation results presented in this paper compare four different active FTC systems. Each FTC system comprises of a pseudospectral based nonlinear model predictive controller. Four different FDI methods have been integrated namely, EKF based, UKF based, IMM-EKF based and IMM-UKF based. The results given show the behaviour of the FTC system both when the loop is closed (ie, the FDI information is fed to the controller) and when the controller is given has no FDI information. The results showed that by using the FDI state estimates to update the NMPC process model tracking performance increased and less demand was placed on the control inputs due to the fact that by closing the loop the NMPC controller was better informed to handle the fault. The UKF based FTC system proved to be the most promising and this is the first time that such a study has been conducted and that these filters have been used in conjunction with a pseudospectral NMPC controller for fault tolerant control outside of the process industry.

5. CONCLUSION

This paper presented a novel approach to active fault tolerant control. It is the first time a UKF filter has been combined with a nonlinear MPC based controller that uses pseudospectral discretisation techniques for the purposes of fault tolerant control.

Four different filters were integrated with the NMPC based controller the EKF, the UKF, the IMM EKF and the IMM UKF filters and the resulting FTC systems were compared. A 2D robot model was used to test and evaluate the different FTC systems. The results showed that in terms of fault detection performance the UKF is the best candidate in a trajectory tracking scenario.

Comparisons were also made between the performance of nonlinear MPC and linear MPC. The results clearly show that for the purposes of reconfigurable fault tolerant control the nonlinear MPC controller has better performance.

The analysis from this work has proven the feasibility of the pseudospectral based NMPC controller design with filter estimates for controller reconfiguration as a viable solution to fault tolerant control. The next phase of this research is to implement the NMPC pseudospectral controller with a UKF based FDI subsystem to an aircraft, for fault tolerant flight control.
