Clinical suspicion of small for gestational age at term

Fetal growth restriction, intra-uterine growth restriction, induction of labour, prenatal ultrasound
Abstract

Background
Small for gestational age (SGA) is a major determinant of poor perinatal outcome. Detecting SGA at term using ultrasound is challenging and we often plan birth based on clinical assessment.

Aims:
To determine the incidence of SGA infants with birthweight <10th centile among women undergoing planned birth at term for suspected small for gestational age (SGA) despite a normal estimated fetal weight (EFW) on ultrasound at 35-37 weeks.

Materials and methods
We performed a retrospective study including all women with a fetal growth ultrasound at ≥35 weeks reporting an EFW ≥10th centile (appropriate for gestational age, AGA) who subsequently had an induction of labour or caesarean birth at ≥37 weeks due to ongoing clinical suspicion of SGA between 2012-2014. The primary outcome was the incidence of SGA newborns using customised centiles.

Results
There were 532 women that had a planned birth for clinical suspicion of SGA during the study period. Of these, 205 (38.5%) had an AGA fetus on ultrasound ≥35 weeks but were subsequently delivered because of a persisting clinical suspicion of SGA on abdominal assessment. 68% (n=139/205) delivered an SGA infant. Furthermore, almost half of these SGA infants (47.5%) had a birthweight <3rd centile. Neonatal outcomes were worse for the SGA infants, with 15.1% (n=21/205) requiring special care nursery compared to 1.5% (n=1/205) of those AGA grown at birth.

Conclusions

This article is protected by copyright. All rights reserved
A reassuring ultrasound with EFW ≥10th centile in the late third trimester should not override clinical concerns of impaired fetal growth at term.
Clinical suspicion of small for gestational age at term

Introduction

Small for gestation age (SGA) is a major determinant of poor perinatal outcome. Defined as a birth weight of < 10th percentile, it is a surrogate marker for fetal growth restriction. It is associated with fetal distress, seizures, cerebral palsy, behavioural problems, hypoglycaemia and perinatal mortality1-4. These adverse outcomes are more pronounced in babies with extremely low birthweight. If women with a growth restricted baby at term are expectantly managed the incidence of extreme SGA doubles,5 hence it seems reasonable to undertake a planned birth in these women. Importantly, if women with SGA are identified and managed appropriately (surveillance and timely delivery) there is evidence that the stillbirth rate can be reduced by half6, 7.

Our current methods for identifying the presence of an SGA fetus at term are modest. Women without risk factors for SGA are screened clinically with abdominal palpation and symphysio-fundal height measurements at prenatal clinic appointments3, 8. If there is clinical concern the fetus may be SGA then an ultrasound is often requested to derive an estimated fetal weight9. This approach to screening was examined in Sovio et al5 which demonstrated selective ultrasound only identified 20% of pregnant women with SGA in the population.

Due to the known inaccuracies of ultrasound at term10 coupled with the serious consequences of misdiagnosing SGA6, 7 some clinicians still recommend planned birth among women where there is ongoing clinical suspicion of SGA at term gestation, despite a normal growth ultrasound. Surprisingly, whether or not this approach identifies considerably more SGA fetuses’ than the expected population incidence of 10% has not been examined.
Thus, we set out to determine rates of SGA among women undergoing planned birth for prenatal clinical suspicion of SGA, despite a normal estimated fetal weight (EFW) on a recent ultrasound.

Materials and methods
We undertook a retrospective study of women having a planned birth at term for SGA despite a normal growth ultrasound at ≥ 35 weeks’ gestation at the Mercy Hospital for Women, a tertiary obstetric hospital in Melbourne, Australia. We included participants who had a planned birth at ≥ 37 weeks for suspected SGA accompanied by an ultrasound EFW ≥ 10th centile at ≥ 35 weeks’ gestation. The ultrasound scans were performed by sonographers or clinicians trained in ultrasound. Ultrasound scans performed by sonographers or clinicians in training were all reviewed by a senior sonographer, radiologist or clinician with a diploma of diagnostic ultrasound. EFW centiles were calculated using the Australian EFW charts recommended for use in our institution. These charts derive an intrauterine growth curve by utilising a coefficient from the birthweights of Australian infants at 40 weeks and placing this into a calculator which was previously published by Mikolajczyk and Hadlock (Figure S1 and Figure S2). Birthweight centiles were derived using the GROW chart customised for the Australian population and for the height and weight of our participants where it was documented. We did not customise for ethnicity as this can be difficult to determine in our population and there is controversy surrounding whether socioeconomic differences may result in birthweight discrepancies between races.

We excluded multiple pregnancies, those where SGA was suspected prior to 35 weeks’ gestation and those complicated by a fetal congenital anomaly (Figure 1).
Clinical practice for suspicion of SGA at term

All pregnant women birthing at our institution have weekly consultations with a midwife or doctor from 36 weeks and symphysiofundal height (SFH) is recorded at each visit to monitor fetal growth. SGA is suspected if there is a static SFH (ie no change on serial weekly measurements) or SFH of < 2 cm than expected for gestation (based on SFH cm = gestational age weeks), or if the uterus is small for gestation as determined by clinical palpation.

If SGA is suspected, women are often referred for a growth ultrasound. It is routine clinical practice in our institution to recommend planned birth before 40 weeks (either via induction of labour or elective caesarean birth) for women with suspected SGA at term. If the ultrasound demonstrates an EFW ≥ 10th centile, and maternal and fetal well-being are normal, then management is usually expectant. However, if a clinical suspicion of impaired fetal growth persists despite an ultrasound EFW ≥ 10th centile, then planned birth may still be recommended at the clinician’s discretion.

Data Collection

We accessed electronic hospital databases containing all planned births between January 2012 to December 2014. We searched these databases using the pre-specified delivery indication of ‘suspected SGA’ to identify participants. Routinely collected obstetric and perinatal data including ultrasound reports were retrieved from electronic and paper hospital records.

Outcomes

This article is protected by copyright. All rights reserved
The primary outcome was the rate of birthweight <10th centile as a proportion of women delivered for suspected SGA following a normal growth ultrasound done ≥ 35 weeks gestation. Birthweight centile was calculated using the GROW calculator customised for the Australian population13, 15. Secondary outcomes included birthweight < 3rd centile, gestation at birth, interval between ultrasound and delivery, the mode of delivery, post-partum haemorrhage, and neonatal admission to the special care nursery or neonatal intensive care.

Statistical analysis

Statistical analysis was performed using GraphPad Prism 7 (GraphPad Software, La Jolla, CA) with a Student’s t-test for continuous variables that approximated a normal distribution and Mann-Whitney U tests for skewed data and a Fisher’s exact test for categorical variables. Data were expressed as a median and interquartile range (IQR) or a percentage of total. Statistical significance was defined as a p value < 0.05.

Ethics

Ethics approval for the project was obtained from the Mercy Hospital for Women Human Research Ethics Committee (approval project number R16/75). As this was a retrospective cohort study, individual patient consent was not required (in accordance with the ethics board).

Results

A total of 532 women with singleton pregnancies had a planned birth for suspected SGA at term during the study period. Of these, 265 were delivered on clinical grounds alone (no ultrasound) with 117 (44.2%) being SGA at birth and we excluded these from further analysis. A further 267 had an ultrasound and of these, 62 (23.2%) were diagnosed with EFW.
Clinical suspicion of small for gestational age at term

< 10th centile. Of this cohort we were able to determine the predictive accuracy of ultrasound. We found that the prevalence of SGA at birth was 68.9% in participants referred for a growth ultrasound and subsequently birthing for suspected SGA. The sensitivity of ultrasound was low at 24.5% however specificity was reasonable at 79.5%. The negative predicative value of ultrasound was similarly low at 32.1% whilst positive predictive value was reasonable at 72.6%. For the purposes of our study we excluded participants that had a planned birth as a result of SGA diagnosed on ultrasound.

Our final cohort thus consisted of 205 women who had an AGA fetus on ultrasound at 35-37 weeks but were induced or had a caesarean section due to ongoing clinical suspicion of growth restriction (Figure 1). Sixty-eight percent (n=139/205) of infants born to women in our cohort had birthweights < 10th centile (Table 1). Almost half of these infants (66/139, 47.5%) had birthweights below the 3rd centile. Importantly outcomes were worse for babies with SGA: 15.1% (n=21/139) SGA babies required special care nursery compared to 1.5% (n=1/66) of those that were normally grown at birth (Table 2).

The demographic characteristics of the cohort are presented in table 1. There were no significant differences in maternal age, parity, body mass index, chronic medical disease or a past history of SGA between the women with AGA and SGA infants. Women with SGA infants had their ultrasound earlier in gestation and had lower EFW centile (20% compared to 30%) and EFW (2478g compared to 2678g) compared with women with AGA infants. Ultrasound measures of placental function (umbilical artery resistance and amniotic fluid index) were similar between the groups (Table 1).
There were no differences in the gestation at delivery of those born SGA median 38.6 (IQR (interquartile range) 38-39.6 weeks) compared to AGA infants median 38.8 weeks (IQR 38 – 39.9 weeks). The length of gestation from ultrasound to delivery was similar between groups at 2.2 (95% CI 1.9, 2.4) weeks in those SGA at birth and 2.1 (95% CI 1.7, 2.4) weeks for those with normal birth weight. Mode of delivery and postpartum complications were also similar between the groups (Table 2).

Discussion

Main findings

This study was designed to assess the accuracy of clinical detection of term SGA in the setting of a normal EFW at 35-37 weeks. We found that clinical judgment was correct in more than two thirds of cases. Detecting SGA at term is paramount as it has the highest population attributable risk to stillbirth. Unfortunately, selective ultrasound only detects 20% of cases of SGA. Our findings highlight the value of continued physical examination to assess fetal growth and the pitfalls of relying on ultrasound alone for detection of fetal growth restriction at term.

We also investigated the overall detection rate of SGA in our cohort that had an ultrasound for suspected SGA. When we added the numbers of participants with correctly diagnosed SGA on ultrasound to those with SGA detected on clinical exam following a normal growth scan, we found our SGA detection rate was 72% (n=193/267). Together, these findings confirm the enduring value of clinical examination and judgment.

Interpretation

This article is protected by copyright. All rights reserved
The mean birthweight centile of the SGA group was very low at 3.88% indicating a group with substantially more severe in utero compromise than the AGA group. While our study was underpowered to measure differences in serious perinatal outcomes such as stillbirth or neonatal mortality, it is well established that perinatal mortality rises exponentially with lower birthweight centile at term and timely identification of SGA fetuses is a key component to preventing stillbirth. The SGA group did have significantly higher morbidity demonstrated through higher rates of special care nursery and neonatal intensive care admission.

The customised birthweight centile of those born at or above the 10th centile was in the lowest quartile at 22%. Thus, participants with planned birth for suspected SGA on clinical grounds were still generally smaller than average for our population. This suggests that clinical examination may also identify babies with reduced growth velocity, not just small size. It is important to identify this group as they are also at increased risk of stillbirth, with a two-fold increase in perinatal death in babies with a birthweight between the 10-25th centile. Furthermore, a reduced growth velocity is associated with a poor pregnancy outcome.

Several population-based studies determining the accuracy of one third-trimester ultrasound compared to clinical examination without ultrasound to detect SGA at term support the utility of clinical examination and highlight the limitations of ultrasound. Al-Amin et al reported clinical examination was significantly better at detecting SGA at 54.5% compared to ultrasound at term at 36.8%. Furthermore, a prospective study comparing clinical assessment to ultrasound in a low-risk pregnancy population found rates of SGA using clinical acumen (27.9%) compared with a single third-trimester ultrasound (24.7%)19. While we did not

This article is protected by copyright. All rights reserved
directly compare the overall detection rate of SGA by ultrasound and clinical assessment in our population, our study provides useful information on the positive predictive value of a clinical diagnosis of SGA when it is discordant with recent ultrasound EFW.

It is possible that the two-week time interval between the ultrasound and birth may have influenced the high rates of SGA observed in our cohort. In the Disproportionate Intrauterine Growth Intervention Trial at Term (DIGITAT)\(^5\), which randomised women with ultrasound-detected fetal growth restriction into planned delivery or expectant management, the group managed expectantly birthed on average 10 days later than those with planned birth and contained twice as many babies < 3\(^{rd}\) centile. This lag time between the ultrasound assessment and delivery in the expectant group in DIGITAT is thought to be responsible for the higher proportion of babies in < 3\(^{rd}\) centile. It is possible that some of our fetuses that were thought to be AGA at 35-37 weeks were indeed at or above the 10\(^{th}\) centile at that time but may have experienced reduced growth velocity in the subsequent two weeks, resulting in a birthweight below the 10\(^{th}\) centile.

One of the strengths of our study is the very tight gestational age range of late third trimester ultrasounds in our cohort median 36.4 (IQR 36.0-37.1) weeks. Due to the inaccuracy of EFW at term\(^0\), fetal growth scans for EFW are not generally performed after 37 weeks in our institution. This means the clinical decision making for the fetuses that were AGA on a 35-37-week ultrasound was not confounded by additional EFW estimations.

The retrospective design meant we were unable to formally define SGA and had to rely on the indication nominated by the clinician for the induction of labour or elective caesarean

This article is protected by copyright. All rights reserved
Clinical suspicion of small for gestational age at term

section. We were unable to assess other factors that may have contributed to planned birth including the women’s preferences and type of practitioner.

We would also note that different methodologies were used to classify EFW and birthweight centiles. The EFW centiles were calculated using an intrauterine growth curve derived from an Australian metropolitan birth cohort\textsuperscript{11} whilst the birthweight centile was calculated using the Australian specific GROW calculator customised for individual maternal height and weight\textsuperscript{15}.

We retained these two methods of assessing fetal growth and birthweight as this was a pragmatic study that assessed clinical management in our institution. Comparison of the parameters used to derive the EFW and birthweight centiles showed general concordance. The mean birthweight used to derive both the intrauterine chart and the Australian population specific GROW chart were similar and we therefore do not think there is much disparity between the two charts. However perhaps slight differences between charts may have contributed to the number of babies born with a birth weight < 3\textsuperscript{rd} centile (47.5\% of those born <10\textsuperscript{th} centile). Our study design was pragmatic, and we opted for this as it reflects current clinical practice.

We have found that two thirds of women who had a planned birth due to suspected SGA following a normal growth ultrasound at 35-37 weeks had an SGA infant, with almost one in two of these infants born < 3\textsuperscript{rd} centile. Therefore, an ultrasound EFW ≥ 10\textsuperscript{th} centile in late third trimester should not override clinical concerns of impaired fetal growth at term. Close observation or planned birth for these fetuses should still be considered.
