ABSTRACT

Introduction Distress is experienced by the majority of cardiac patients, yet no cardiac-specific measure of distress exists. The aim of this project is to develop and validate the Cardiac Distress Inventory (CDI). Using the CDI, health professionals will be able to identify key clusters of psychological, emotional and social concern to address with patients, postcardiac event.

Methods and analysis An item pool will be generated through: identification of items by a multidisciplinary group of clinician researchers; review of generic and condition-specific distress measures; focus group testing with cardiac rehabilitation professionals; feedback from patients. The COSMIN (Consensus-based Standards for the selection of health Measurement INstruments) criteria will be used to inform the development of the methodology for determining the CDI’s psychometric properties. The item pool will be tested with 400 cardiac patients and responses subjected to exploratory factor analysis, Rasch analysis, construct validity testing and latent class analysis. Receiver operating characteristic analysis will be used to identify the optimal CDI cut-off score for distinguishing whether a person experiences clinically significant distress.

Ethics and dissemination Approved by the Monash Health Human Research Ethics Committee (approval number—RES-19-0000631L-559790). The CDI will be made available to clinicians and researchers without charge. The CDI will be translated for use internationally. Study findings will be shared with cardiac patient support groups; academic and medical communities via publications and presentations; in the training of cardiac secondary prevention professionals; and in reports to funders. Authorship for publications will follow the uniform requirements for manuscripts submitted to biomedical journals.

BACKGROUND

Conceptualisation of cardiac distress
As high prevalence conditions, much attention has been paid to the measurement and understanding of anxiety and depression as consequences of cardiac events. However, less attention has been given to the phenomenon of ‘cardiac distress’, which many patients experience after acute coronary events such as acute myocardial infarction (AMI), unstable angina or coronary artery bypass graft surgery (CABGS). In an earlier paper, we discussed the conceptualisation of cardiac distress and defined it as:

a persistent negative emotional state rather than a transient state; involving multiple psychosocial domains; that challenges a patient’s capacity to cope with living with their heart condition, the treatment of the condition, and the resultant changes to daily living; and challenges the person’s sense of self and future orientation.1

A number of previous studies have attempted to examine the relationship between postcardiac event distress, symptom severity and mortality in relation to a range of specific heart conditions2 3 and procedures,4 5 following cardiac rehabilitation,6 and in cardiovascular disease more generally.7 A common characteristic of these studies, however, is the use of terms such as ‘distress’ without explicit definition. In some cases, distress is simply defined as being
that which is measured by an instrument deemed to measure distress such as the Hospital Anxiety and Depression Scale, the General Health Questionnaire or the Kessler Psychological Distress Scale. Typically, these studies view psychological or emotional distress as a simple combination of anxiety and depression, as does a recent analysis of postcardiac event psychological distress trajectories.

A small number of studies of cardiac patients, however, widen this narrow view of distress by adding other psychosocial constructs to ‘anxiety plus depression’, including stress and stressful life events, fear of death, hostility; vital exhaustion and reduced quality of life, vulnerabilities such as lack of pleasant events, dysfunctional attitudes, role transitions and poor dyadic adjustment, feelings of helplessness, loss of control and pain; and psychological well-being. In other chronic conditions such as cancer, diabetes and rheumatic conditions, fear of disease progression has also been identified as an important reason for distress. This future-oriented component of distress is expressed in an extreme form in cardiac disease-induced post-traumatic stress disorder (CDI-PTSD) with Vilchinsky and colleagues noting that fear of death dominates the experience of patients with CDI-PTSD.

Traumatic components of a cardiac event are the abruptness of the event, the risk of death and a strong sense of loss of control and helplessness during the event. These reactions coupled with the experience of surgery can lead to significant anxiety associated with death or recurrence, as well as anger, sadness and grief, all symptoms associated with PTSD. Differentiating distress from CDI-PTSD, however, are a range of additional psychosocial factors such as challenges to people’s coping with daily living, the impact of social isolation, role transitions and challenges, and cognitive issues.

The ‘cardiac blues’

A broader approach to understanding the complexity of the psychological and emotional impacts of a cardiac event is evidenced in the concept of the ‘cardiac blues’, which describes a range of emotional responses to an acute cardiac event. It has been suggested that almost all patients experience at least some symptoms of the cardiac blues at the time of, or soon after, an acute cardiac event. Common emotions include shock, low or fluctuating mood, sadness, worry, guilt and anger. Mood changes are displayed by tiredness, irritability, tearfulness, loss of pleasure in usual activities, withdrawal from others, early waking and other sleep disturbance, and changes in appetite and sex drive. Cognitive changes that typically co-occur include confusion and forgetfulness, inability to concentrate, nightmares, reduced self-esteem, concerns about role changes, particularly regarding paid work, physical health and independence, and pessimism about the future. Although generally a transient condition, if the cardiac blues does not resolve within around 2 months of the cardiac event, the psychological and emotional impact of the event can result in persistent cardiac distress.

Measuring condition-specific distress

Both the oncology and diabetes fields have at least a two-decade long history of screening and psychosocial intervention for condition-specific distress. For oncology, this is reflected in the National Comprehensive Cancer Network Guidelines for Distress Management, where distress is considered to be a multifactorial unpleasant experience of a psychological (ie, emotional, behavioural, cognitive), social, spiritual and/or physical nature that may interfere with the ability to cope effectively with cancer, its physical symptoms or its treatment. An excellent earlier attempt to conceptualise diabetes distress so that it could be recognised and addressed in nursing practice has recently been extended by Dennick and colleagues. They characterise distress as a range of negative emotional responses, such as worry, fear, frustration, guilt, sadness, anger, to aspects of living with and managing the condition, balanced against an appraisal of available coping resources.

Cardiac-specific measures of the psychosocial impact of cardiac events

The cardiac field also has a two-decade long history of attempts to measure specific aspects of the psychological and emotional impact of cardiac events. Examples of cardiac-specific measures include the Cardiac Depression Scale, the Cardiac Event Threat Questionnaire, the Cardiac Anxiety Questionnaire, the MacNew Quality of Life measure, the Screening Tool for Psychological Distress (STOP-D), the Myocardial Infarction Dimensional Assessment Scale (MIDAS) and the European Society of Cardiology (ESC) brief (15-item) screen of psychosocial risk factors for cardiac patients. These measures collectively assess a range of features associated with cardiac distress such as impaired quality of life, anxiety, depression, fear, death anxiety, illness-related dependency, feeling unable to cope, work and family stress, worrying levels of pain, social isolation and low perceived social support, anger and type D personality. However, there remains no single comprehensive assessment of cardiac distress as we have defined it. While the Joint ESC Guidelines psychosocial screen is an excellent start in this regard and provide an indicator for a health professional that psychosocial support is warranted, a measure is needed that enables a cardiac psychology professional to clearly identify priority areas in order to offer a timely tailored intervention for a distressed patient.

Using the Cardiac Distress Inventory (CDI), health professionals will be able to identify key clusters of psychological, emotional and social concern to address with patients, post-cardiac event at a depth not afforded by one
or two questions per construct as in the ESC core questions for the assessment of psychosocial risk factors in clinical practice. For good clinical intervention, we need to know not just that people are anxious, but they are anxious about. Similarly, what is it that they fear: death, loss of function, loss of role, loss of intimacy? Achieving this degree of granularity to guide intervention is the point of the CDI.

**Aims**

The aims of the present study are as follows:
1. To develop and validate the CDI.
2. To develop a short form screening tool version of the CDI.

**METHODS**

The methods described in this protocol for development and validation of the CDI conform, we believe, to the ‘best practices’ for undertaking such a task, outlined by Boateng and colleagues.

The methods described in this protocol for development and validation of the CDI conform, we believe, to the ‘best practices’ for undertaking such a task, outlined by Boateng and colleagues.

**Item generation**

There are six steps in the item generation procedure:
1. Initial generation of items by a multidisciplinary group of researchers and clinicians including the disciplines of nursing, psychiatry, behavioural health, psychology and cardiology.
2. Review of generic and condition-specific distress measures to identify the elements comprising the construct of ‘distress’ in those measures and to identify items that could be adapted for the CDI.
3. Review of cardiac-specific measures incorporating elements of distress as defined by the present authors.
4. Review of items for appropriateness for a postoperative cardiac population by the multidisciplinary investigator group.
5. Focus group testing with two multidisciplinary groups of cardiac rehabilitation (CR) professionals; experienced practitioners undertaking intensive training in cardiac rehabilitation through the Australian Centre for Heart Health and the National Executive of the Australian Cardiovascular Health and Rehabilitation Association (ACRA).
6. Consultation with, and feedback from, cardiac patients (key informants) on the structure and content of the CDI.

**Patient and public involvement**

The need for a comprehensive measure of cardiac-related distress has been identified by the multidisciplinary clinician researcher members of the CDI development group, through their clinical practice in provision of psychosocial support to cardiac patients. This need has been endorsed by the authors’ consultations with both individual patients and patient support groups such as the hospital-based or regionally based Heartbeat programmes such as Heartbeat Victoria. As evident from step 6 in the item generation procedure, patients will be consulted as key informants about the structure and content of the CDI. Only after this process of consultation is complete will the CDI item pool be tested with 400 cardiac patients.

**Ethics approval and dissemination of the CDI measure**

This study has been approved by the Monash Health Human Research Ethics Committee (approval number—RES-19-000631L-559790) to run from May 2020 until May 2022.

The result of the CDI development project, the psychometrically sound CDI, will be made available to clinicians and researchers without charge, but with a request that data collected in studies using the measure be made available for aggregation and analysis in future. The CDI will also be translated for use with clinical populations internationally with reporting of the psychometric properties of those versions. Confirmed translations will be Italian, Hebrew, Arabic, Farsi and Spanish. Methods for translation vary, but we will adopt the following strategy. The CDI will be translated independently by two bilingual cardiac psychologist clinicians/researchers. These translations will then be back translated into English by a bilingual psychologist independent of the two original translators and not familiar with the CDI study. These back translations will be reviewed by a subgroup of the investigators. Discrepancies will be resolved by consensus between the original translators and the review subgroup.

Study findings will be shared with community members, particularly cardiac patient support groups such as the Heartbeat peer support groups and their equivalents internationally; academic and medical communities via publications and presentations in which authorship will follow the uniform requirements for manuscripts submitted to biomedical journals. An online course and/or webinar on the CDI rationale and use will be provided at no cost by the Australian Centre for Heart Health. The short form will be made available on the website of the Australian Centre for Heart Health for completion by patients to self-screen with suggestions for follow-up psychological support where significant distress is indicated.

**CDI design**

Items generated through the process outlined above will be reworded where appropriate to ensure relevance to the measurement of cardiac distress and appropriateness of fit with the following instruction and response set:

*Living with a heart condition can sometimes be difficult. Listed below are some issues that people living with a heart condition may experience.*

Please indicate whether or not you have experienced each issue during the past four weeks by checking ‘Yes’ or ‘No’. For each item you have checked ‘Yes’, indicate how much distress this issue has caused you for the past four weeks, from 0 to 3, where ‘0’ is no distress and ‘3’ is severe distress.
Trialling of the questionnaire for item reduction
Sample size required for trial

Recommendations of sample size for exploratory factor analysis in instrument development are that there should be at least five cases for each item in the instrument being used. Rasch modelling for exploratory purposes should be based on at least n=100 and preferably N=250. For the reliability and validation study, power calculations were conducted using GPower. Given a probability level of 0.05, an anticipated effect size of 0.5 and a desired statistical power level of 0.8, a sample size of N=66 is required per group. A summary of the steps and the number required for each step in the analysis are provided in table 1.

Inclusion and exclusion criteria

Eligible patients will be those who have had an acute coronary event namely acute coronary syndrome (ACS), AMI or CABGS in the previous 6 months and who are attending either a CR programme or an outpatient clinic at a participating hospital. Patients who do not have adequate English language proficiency to read and understand the Patient Information and Consent Form and questionnaire will be excluded.

AF, atrial fibrillation; AMI, acute myocardial infarction; CABGS, coronary artery bypass graft surgery; K6, Kessler 6; LCA, latent class analysis.
Demographic questionnaire: Basic sociodemographic (eg, age, sex, marital status, living arrangement) and cardiac event-related information (event type, date of event) will be collected.

Emotion thermometers: The emotion thermometers are single-item measures of distress (DT), anxiety (AnxT), depression (DepT) and anger (AngT). They consist of a ‘thermometer’ with numerals displayed vertically from 0 to 10. Patients rate their distress ‘over the last week’, with 0 indicating ‘no distress’ and 10 indicating ‘high distress’. A total score from all four mood thermometers (ETsum) indicates overall emotional problems. These thermometers, based on the NCCN cancer distress thermometer (DT), have been shown to be a clinically sensitive measure of distress in patients with mixed cardiovascular conditions.

Patient Health Questionnaire-4 (PHQ-4): The PHQ is a validated brief screener (four items) for anxiety and depression, which combines the Patient Health Questionnaire-2 (PHQ-2) and the Generalised Anxiety Disorder-2 (GAD-2). Total scores range from 0 to 12, with 0 indicating ‘no distress’ and 12 indicating ‘severe distress’.

Kessler Psychological Distress Scale-6 (K6): The Kessler 6 is a brief measure of psychological distress, which has been validated in an Australian general population. The K6 is both an effective screening measure and an indicator of distress severity. Scores range from 6 to 30, with lower scores indicating higher levels of distress.

Screening Tool for Psychological Distress (STOP-D): This is a five-item, evidence-derived self-report measure generating severity scores for depression, anxiety, stress, anger and poor social support. The screening tool has been tested with patients before and after heart transplant, patients in cardiac rehabilitation and adults with congenital heart disease.

STATISTICAL ANALYSIS FOR THE TRIAL
Part A—Establishing dimensions of the CDI
Principal component analysis (PCA) using SPSS v.26 will be used to assess the dimensions of the CDI. PCA is commonly used in the development of new instruments to provide early indications of possible dimensions before Rasch analysis is attempted. PCA is used to extract the factors followed by oblique rotation of factors using Oblimin rotation (delta=0). Kaiser’s criterion, which retains eigen values above 1, will be used to guide the identification of relevant factors. A second step in the PCA is to conduct Horn’s parallel analysis, considered one of the most accurate approaches to estimate the number of components. The size of eigen values obtained from PCA is compared with those obtained from a randomly generated data set of the same size. Only factors with eigen values exceeding the values obtained from the corresponding random data set are retained for further investigation.

Part B—Eliminating items per dimension of the CDI
Rasch analysis is a mathematical technique used to evaluate a latent variable not measurable directly from a set of categorical items. Rasch methods can be used to assess the extent to which individual items represent the underlying construct that an instrument intends to measure. The Rasch model chosen for this analysis, the Partial Credit Model, is applicable to polytomous rather than dichotomous data and is therefore suitable for Likert scales and response ratings.

Rasch analysis will be conducted using RUMM2030 software (RUMM Laboratory Pty, Perth, Australia). Three statistics are considered to determine the degree of fit for each CDI scale: overall fit, individual person fit and individual item fit. Adequate overall fit of the CDI to the Rasch model is indicated by a non-significant Bonferroni adjusted $\chi^2$ probability value. Satisfactory overall item and individual fit for each scale will be determined by a fit residual SD value of ≤1.5. Individual item fit is indicated by two statistics: fit residual values and $\chi^2$ probability values. Item fit residual values −2.5 to 2.5 indicate adequate fit. Above this range (underfit) suggests deviation from the model, below (overfit) suggests that some items in the scale are similar to each other. A perfect model fit would be reflected by residuals with a mean of 0.00 and an SD of 1.00. Any misfitting item in terms of infit/outfit is discarded and the analysis re-run. This iterative process is continued until no further misfit is observed.

The Rasch analysis will produce the Person Separation Index (PSI), which indicates the degree to which study participants can be differentiated into certain groups (PSI range 0–1). Values for PSI of 0.8 are acceptable. A sample size of at least 100 patients is required to perform a Rasch analysis, which can estimate an acceptable PSI value.

Statistical significance will be considered at the 5% level, and Bonferroni correction for multiple testing will be applied where appropriate.

Psychometric properties of the final CDI
The COSMIN (Consensus-based Standards for the selection of health Measurement Instruments) criteria for evaluating the methodological quality of health-related patient-reported outcomes will be used to inform the development of the methodology for determining the psychometric properties as far as possible.

Reliability
Internal consistency of the CDI will be determined using Cronbach’s alpha and evaluation of the PSI from the Rasch analysis.

Validity
Scale comparisons will be used to investigate the concurrent convergent validity of the CDI. Pearson correlation coefficients will be calculated to explore the association between CDI scores and the measure that is commonly used in clinical practice to assess distress, the six-item K6. Subscale scores of the CDI will be compared with K6.
scales where appropriate. We will assess the discriminant validity and predictive validity of the CDI by assessing whether it distinguishes between patients scoring high and low on the K6, using the Australian scoring cut-off of 19 to indicate probable serious mental illness. Again, both CDI total and factor scores will be investigated. It is not possible to use a measure of cardiac distress for validity testing as no such measure exists.

Pearson correlation coefficients will also be calculated to explore the association between CDI scores and the PHQ-4. Normative data are available from a nationally representative face-to-face household survey sample of 5030 people, conducted in Germany in 2006. The measure has been translated and validated in Hispanic populations, for example, and has been used in studies of cancer patients and emergency department patients. As far as the authors are aware, no validation study of the PHQ-4 has been undertaken with cardiac patients.

Comparison of CDI scores will also be conducted between the various types of cardiac patients (eg, AMI vs CABGS). Comparison of groups will be conducted via analysis of variance.

Latent class analysis
Latent class analysis (LCA) will be used in order to describe groups of participants that differ in their response patterns to the CDI. LCA explains individual differences in response patterns by means of a given number of latent classes (subgroups of participants). LCA estimates the size of the classes and a membership probability for each participant within each class and will be performed using Mplus V.6.0. To select the most parsimonious number of classes and maximise model fit, a series of latent class models will be applied to the data. First, the simplest 1-class model (all patients are assumed to have the same pattern of cardiac distress) will be applied to the data, followed by successive models with a unitary increase in the number of latent classes (up to eight). Model solutions are evaluated on the basis of their Bayesian information criterion (BIC) and entropy. The BIC has been shown to be a robust indicator of model fit, with lower values indicative of better model fit. BIC will be used in preference to Akaike information criteria, as the latter has been shown to overextract classes in simulation models. The association of CDI latent class membership with CDI scale scores, sociodemographic characteristics, diagnosis and K6 distress scores will also be examined using Mplus. Mplus generates overall values to assess significant associations between variables as well as unadjusted values for exploratory post hoc analysis.

Development of a short form CDI for screening purposes
A shorter version of the CDI, the CDI-S, will then be created. Importantly, item reduction based on rigorous methodological guidelines is necessary to maintain validity when shortening composite measurement scales. In addition, there are a number of ways to achieve item reduction. In light of these two points, we will use two methods to develop the short form screening tool—a clinically oriented method and a statistically driven method. A concept-retention approach will create a short version of the original measure by selection of the top performing item in each domain to become part of the short, concept-retention version. Rasch analysis as used in a number of health-related item reduction exercises will also be employed. The Rasch analysis and psychometric evaluation of the CDI-S will follow the format described by Nishigami and colleagues. Both versions of the CDI-S will then be field tested.

Thermometer testing
Receiver operating characteristic (ROC) analysis will be used to identify the optimal CDI scale cut-off score for distinguishing whether a person experiences clinically significant distress as defined by the established cut-off thresholds for ETsum (the sum of all four mood thermometers). The area under the curve (AUC) will be used to estimate the overall discriminative accuracy of the CDI scale cut-off score relative to the established cut-off scores of ETsum (a score >14 indicates moderate and >20 indicates severe emotional problems). Using qualitative guidelines for interpreting AUC values, namely AUC ≤0.70 as acceptable discrimination, AUC ≤0.80 as good discrimination and AUC ≤0.90 as excellent discrimination, ROC curves will be used to show the trade-off between the sensitivity (true-positive rate) and specificity (true-negative rate) for every possible cut-off score of the CDI scale.

TIMELINE
Months 1–2: staff recruitment, CR site recruitment and liaison; months 3–18: administration of the full item pool draft CDI to patients attending CR or outpatient appointments; months 19–21: completion of data analysis; months 22–24: writing up the study findings will be a continuous activity with completion in these months.

SUMMARY
Cardiac distress is complex, and various aspects of cardiac distress have been shown to be common among cardiac patients. Before cardiac distress can be treated effectively, it needs to be properly measured by a reliable, valid and sensitive instrument. Stress is increasingly being recognised as a prognostic factor in those with pre-existing cardiovascular or cerebrovascular disease and stress management in CR shows promise. Even so, we are yet to see the totality of cardiac distress, in all of its complexity, being addressed in this way.

The primary aim of the project, therefore, is to develop a new clinical measure, which health professionals can use to identify and assess cardiac distress. They can use the fine-grained assessment provided by this unique measure to structure psychological and emotional interventions.
to intervene in cases of persistent distress in patients, following a cardiac event. No such measure currently exists.

While physical recovery remains the highest priority in preventive cardiology, psychological recovery is now considered a primary concern for health professionals working in CR and secondary prevention. The prevalence of clinical anxiety and depression in people who have had a cardiac event is up to four times higher than in the general population; however, both the prevalence and the nature of the broader concept of cardiac-related distress remain unknown. Post-event psychological problems confer an increased mortality risk for patients, highlighting the importance of identifying distressed patients early in order to ensure appropriate treatment is received. The new CDI will not only enhance clinicians’ ability to identify distressed patients but will also enable them to identify the specific nature of the distress, thereby optimising their ability to provide timely support targeted to the specific psychosocial needs of the patient. The new CDI has the potential to ensure that patients are provided with the specific support they require in their psychosocial recovery after a cardiac event and, in doing so, has the potential to improve their quality of life, enhance their behaviour change efforts and ultimately extend their survival.

Acknowledgements The authors would like to acknowledge the generous posthumous gift by Ms Angela Anita Reid to the Australian Centre for Heart Health which is funding this project.

Contributors AJ drafted the article with MLG drafting the psychometric testing component. MRogerson, MLG, DT, CS, MA, JA, RH, MReciti and BMH made contributions to the resulting draft. All authors approved the final version.

Funding The authors have not declared a specific grant for this research from any funding agency in the public, commercial or not-for-profit sectors.

Competing interests None declared.

Patient consent for publication Not required.

Provenance and peer review Not commissioned; externally peer reviewed.
